Contents

Contributors	x
Preface	xvii
General websites	xviii
1. Adhesion, Bacterial <i>Matthew A. Mulvey and Scott J. Hultgren</i>	1
2. Agrobacterium and plant cell transformation <i>Peter J. Christie</i>	10
3. Antibiotic resistance in bacteria <i>Julian Davies and Vera Webb</i>	25
4. Antifungal agents <i>Ana Espinel-Ingroff</i>	47
5. Antisense RNAs <i>Andrea Denise Branch</i>	68
6. Antiviral agents <i>Richard J. Whitley</i>	84
7. Archaea <i>Paul Blum and Vidula Dikshit</i>	108
8. Attenuation, Transcriptional <i>Charles Yanofsky</i>	117
9. <i>Bacillus subtilis</i> , Genetics <i>Kevin M. Devine</i>	126
10. Bacteriophages <i>Hans-Wolfgang Ackermann</i>	135
11. Biocides (Nonpublic health, Nonagricultural antimicrobials) <i>Mohammad Sondossi</i>	147
12. Biofilms and biofouling <i>Karen T. Elvers and Hilary M. Lappin-Scott</i>	161
13. Biological warfare <i>James A. Poupard and Linda A. Miller</i>	168
14. Bioluminescence, Microbial <i>J. Woodland Hastings</i>	180

15.	Bioreactors <i>Larry E. Erickson</i>	189
16.	Bioremediation <i>Joseph B. Hughes, C. Nelson Neale, and C. Herb Ward</i>	196
17.	Biosensors <i>Yoko Nomura and Isao Karube</i>	216
18.	Cell membrane: structure and function <i>Robert J. Kadner</i>	222
19.	Cell Walls, Bacterial <i>Joachim-Volker Höltje</i>	239
20.	Chemotaxis <i>Jeff Stock and Sandra Da Re</i>	251
21.	Chromosome, Bacterial <i>Karl Drlica and Arnold J. Bendich</i>	259
22.	Conjugation, Bacterial <i>Laura S. Frost</i>	271
23.	Crystalline bacterial cell surface layers (S layers) <i>Uwe B. Sleytr and Paul Messner</i>	286
24.	Culture collections and their databases <i>Mary K. B. Berlyn</i>	294
25.	Developmental processes in bacteria <i>Yves V. Brun</i>	314
26.	Diversity, Microbial <i>Charles R. Lovell</i>	326
27.	DNA repair <i>Lawrence Grossman</i>	340
28.	DNA replication <i>James A. Hejna and Robb E. Moses</i>	350
29.	DNA restriction and modification <i>Noreen E. Murray</i>	358
30.	DNA sequencing and genomics <i>Brian A. Dougherty</i>	371
31.	Ecology, Microbial <i>Michael J. Klug and David A. Odelson</i>	381
32.	Emerging infections <i>David L. Heymann</i>	387
33.	Energy transduction processes: from respiration to photosynthesis <i>Stuart J. Ferguson</i>	394
34.	Enteropathogenic bacteria <i>Farah K. Bahrani-Mougeot and Michael S. Donnenberg</i>	403
35.	<i>Escherichia coli</i> and <i>Salmonella</i> , Genetics <i>K. Brooks Low</i>	415

36.	Exotoxins <i>Joseph T. Barbieri</i>	427
37.	Extremophiles <i>Ricardo Cavicchioli and Torsten Thomas</i>	436
38.	Fimbriae, Pili <i>Matthew A. Mulvey, Karen W. Dodson, Gabriel E. Soto, and Scott J. Hultgren</i>	454
39.	Flagella <i>Shin-Ichi Aizawa</i>	470
40.	Food-borne illnesses <i>David W. K. Acheson</i>	480
41.	Fungal infections, Cutaneous <i>Peter G. Sohnle and David K. Wagner</i>	499
42.	Fungal infections, Systemic <i>Arturo Casadevall</i>	507
43.	Gastrointestinal microbiology <i>T. G. Nagaraja</i>	514
44.	Genetically modified organisms: guidelines and regulations for research <i>Sue Tolin and Anne Vidaver</i>	526
45.	Genomes, Mapping of Bacterial <i>J. Guespin-Michel and F. Joset</i>	536
46.	Germ-free animal techniques <i>Bernard S. Wostmann</i>	547
47.	Gram-negative anaerobic pathogens <i>Arthur O. Tzianabos, Laurie E. Comstock, and Dennis L. Kasper</i>	554
48.	Gram-negative cocci, Pathogenic <i>Emil C. Gotschlich</i>	562
49.	Heat stress <i>Christophe Herman and Carol A. Gross</i>	574
50.	Horizontal transfer of genes between microorganisms <i>Jack A. Heinemann</i>	582
51.	Human immunodeficiency virus <i>Luc Montagnier</i>	591
52.	Identification of bacteria, Computerized <i>Trevor N. Bryant</i>	602
53.	Industrial fermentation processes <i>Thomas M. Anderson</i>	613
54.	Insect's symbiotic microorganisms <i>A. E. Douglas</i>	626
55.	Iron metabolism <i>Charles F. Earhart</i>	637
56.	Lipopolysaccharides <i>Chris Whitfield</i>	645

57.	Methanogenesis <i>Kevin R. Sowers</i>	659
58.	Methylotrophy <i>J. Colin Murrell and Ian R. McDonald</i>	680
59.	Nitrogen cycle <i>Roger Knowles</i>	690
60.	Nitrogen fixation <i>L. David Kuykendall, Fawzy M. Hashem, Robert B. Dadson, and Gerald H. Elkan</i>	702
61.	Nodule formation in legumes <i>Peter H. Graham</i>	715
62.	Nutrition of microorganisms <i>Thomas Egli</i>	725
63.	Oral microbiology <i>Ian R. Hamilton and George H. Bowden</i>	739
64.	Osmotic stress <i>Douglas H. Bartlett and Mary F. Roberts</i>	754
65.	Outer membrane, Gram-negative bacteria <i>Mary J. Osborn</i>	767
66.	Oxidative stress <i>Pablo J. Pomposiello and Bruce Demple</i>	775
67.	pH Stress <i>Joan L. Slonczewski</i>	781
68.	Plant pathogens <i>George N. Agrios</i>	789
69.	Plasmids, Bacterial <i>Christopher M. Thomas</i>	808
70.	Polymerase chain reaction (PCR) <i>Carol J. Palmer and Christine Paszko-Kolva</i>	824
71.	Prions <i>Christine Musahl and Adriano Aguzzi</i>	829
72.	Protein secretion <i>Donald B. Oliver and Jorge Galan</i>	842
73.	Quorum sensing in gram-negative bacteria <i>Clay Fuqua</i>	859
74.	Recombinant DNA, Basic procedures <i>Judith W. Zyskind</i>	870
75.	Sexually transmitted diseases <i>Jane A. Cecil and Thomas C. Quinn</i>	879
76.	Skin microbiology <i>Morton N. Swartz</i>	899
77.	Soil microbiology <i>Kate M. Scow</i>	914

78.	SOS response <i>Kevin W. Winterling</i>	927
79.	Space flight, effects on microorganisms <i>D. L. Pierson and S. K. Mishra</i>	934
80.	Sporulation <i>Patrick J. Piggot</i>	942
81.	Starvation, Bacterial <i>A. C. Matin</i>	951
82.	Strain improvement <i>Sarad Parekh</i>	960
83.	Sulfur cycle <i>Piet Lens, Marcus Vallero, and Look Hulshoff Pol</i>	974
84.	Transcriptional regulation in prokaryotes <i>Orna Amster-Choder</i>	984
85.	Transduction: host DNA transfer by bacteriophages <i>Millicent Masters</i>	1000
86.	Transformation, Genetic <i>Brian M. Wilkins and Peter A. Meacock</i>	1012
87.	Transposable elements <i>Peter M. Bennett</i>	1025
88.	Two-component systems <i>Alexander J. Ninfa and Mariette R. Atkinson</i>	1042
89.	Vaccines, Bacterial <i>Susan K. Hoiseth</i>	1053
90.	Vaccines, Viral <i>Ann M. Arvin</i>	1063
91.	Viruses <i>Sondra Schlesinger and Milton J. Schlesinger</i>	1071
92.	Viruses, Emerging <i>Stephen S. Morse</i>	1084
93.	Yeasts <i>Graeme M. Walker</i>	1102
	Index	1115

Contributors

David W. K. Acheson

Center for Food Safety and Applied Nutrition,
Food and Drug Administration,
Rockville, MD 20740, USA

H.-W. Ackermann

Department of Medical Biology, Laval University,
Local 2332, Pav. Ferdinand Vandry, Laval, Quebec,
Canada G1K 7P4

George N. Agrios

Department of Plant Pathology, University of
Florida, 1453 Fifield Hall, P.O. Box 110680,
Gainesville, FL 32611, USA

Adriano Aguzzi

Institute of Neuropathology, University of Zurich,
University Hospital of Zürich, Schmelzbergstrasse
12, Zurich CH-8091, Switzerland

Shin-Ichi Aizawa

Soft Nano-Machine Project, CREST,
Japan Science and Technology Agency,
1064-18 Takahori, Hirata, Takanezawa,
Shioya-gun, Tochigi 329-1206, Japan

Orna Amster-Choder

Department of Molecular Biology,
Hebrew University School of Medicine,
P.O. Box 12272, Bldg. 3, 2nd Floor, Room 34,
Jerusalem 91120, Israel

Thomas M. Anderson

Microbiology Manager, Archer Daniels Midland
BioProducts, P.O. Box 1470, Decatur, IL 62525, USA

Ann M. Arvin

Department of Pediatrics, Stanford University
School of Medicine, Mailcode 5208, 300 Pasteur
Drive, G-312A Stanford, CA 94305, USA

Mariette R. Atkinson

Department of Biological Chemistry,
University of Michigan Medical School,
4310 Med Sci I, 1301 Catherine, Ann Arbor,
MI 48109-0606, USA

Farah K. Bahrani-Mougeot

Department of Medicine, University of Maryland
School of Medicine, MSTF 90, 656 W Baltimore St.,
Baltimore, MD 21201-1559, USA

Joseph T. Barbieri

Department of Microbiology, Medical College of
Wisconsin, P.O. Box 26509, 8701 Watertown Plank
Rd., Milwaukee, WI 53226-0509, USA

Douglas H. Bartlett

Center for Marine Biotechnology and
Biomedicine, University of California,
San Diego, Scripps Institution of Oceanography,
9500 Gilman Drive, Dept 0202, La Jolla,
CA 92093-0202, USA

Arnold J. Bendich

Professor of Botany and Genetics, Department of
Biology, 522 Hitchcock Hall, University of
Washington, Box 351800, Seattle, WA 98195, USA

Peter M. Bennett

Department of Pathology and Microbiology,
University of Bristol, School of Medical Sciences,
University Walk, Bristol BS8 1TD, UK

Mary K.B. Berlyn

Department of Biology, Yale University, 355-OML,
165 Prospect St., New Haven, CT 06520-8104, USA

Paul Blum

George Beadle Center for Genetics,
Nebraska University-Lincoln, P.O. Box 880666,
Lincoln, NE 68588-066, USA

Andrea D. Branch

Division of Liver Diseases, Department of Medicine,
Mount Sinai Medical Center, Recanati/Miller
Transplantation Institute, One Gustave L. Levy
Place, Box 1633, New York, NY 10029-6574, USA

Yves V. Brun

Department of Biology, Indiana University,
Jordan Hall, Bloomington, IN 47405, USA

Trevor N. Bryant

Medical Statistics and Computing, University
of Southampton, Southampton General Hospital,
Tremona Rd, Southampton SO16 6YD, UK

George H. Bowden

Department of Oral Microbiology, University of
Manitoba, Faculty of Dentistry, 780 Bannatyne
Avenue, Winnipeg, Manitoba, Canada R3E 0W2

Arturo Casadevall

Department of Medicine, Infectious Diseases,
Albert Einstein College of Medicine,
Golding Bldg. Rm. 701, 1300 Morris Park Avenue,
Bronx, NY 10461, USA

Ricardo Cavicchioli

Department of Microbiology and Immunology,
University of New South Wales, Sydney, NSW 2052,
Australia

Jane A. Cecil

The Johns Hopkins University, Ross Research
Building 1159, 720 Rutland Avenue, Baltimore,
MD 21205-2196, USA

Peter J. Christie

Department of Microbiology and
Molecular Genetics, University of Texas Health
Science Center, 6431 Fannin St., Houston,
TX 77030-1501, USA

Laurie E. Comstock

Channing Laboratory, Harvard Medical School,
181 Longwood Avenue, Boston,
MA 02115-5899, USA

Sandra Da Re

Department of Molecular Biology, Princeton University,
330 Lewis Thomas Lab, Princeton, NJ 08544, USA

Robert B. Dadson

University of Maryland, Eastern Shore,
Princess Anne, Maryland, USA

Julian Davies

Department of Microbiology and Immunology,
University of British Columbia, Vancouver,
British Columbia, Canada

Bruce Demple

Department of Cancer Cell Biology, Harvard School
of Public Health, Bldg. 1 Floor 6, 665 Huntington
Avenue, Boston, MA 02115-6021, USA

Kevin M. Devine

Department of Genetics, Trinity College, Dublin,
Lincoln Place Gate, Dublin 2, UK

Vidula Dixit

George Beadle Center for Genetics, Nebraska
University-Lincoln, P.O. Box 880666, Lincoln, NE
68588-0666, USA

Karen W. Dodson

Department of Molecular Microbiology, Washington
University School of Medicine, Campus Box 8230,
660 S Euclid Avenue, 8230, St. Louis,
MO 63110-1010, USA

Michael S. Donnenberg

Department of Medicine, University of Maryland
School of Medicine, MSTF 90, 656 W Baltimore St.,
Baltimore, MD 21201-1559, USA

Brian A. Dougherty

Department of Applied Genomics,
Bristol-Myers Squibb Company, Pharmaceutical
Research Institute, 5 Research Parkway,
Wallingford, CT 06492-7660, USA

Angela E. Douglas

Department of Biology, University of York,
P.O. Box 373, York YO1 5YW, UK

Karl Drlica

Public Health Research Institute,
225 Warren Street, Newark, NJ 07103

Charles F. Earhart

Department of Microbiology, University of Texas,
ESB 226, A5000, 24th St. & Speedway, Austin,
TX 78712-1095, USA

Thomas Egli

Department of Microbiology, Swiss Federal Institute
for Environmental Science and Technology, BU-D04,
Ueberlandstrasse 133, Dübendorf CH-8600,
Switzerland

Gerald H. Elkan

Department of Microbiology, North Carolina State
University, Raleigh, NC 27605, USA

Karen T. Elvers

Hatherly Labs, University of Exeter, Exeter,
Prince of Wales Road, Devon EX4 4PS, UK

Larry E. Erickson

Department of Chemical Engineering, Kansas State University, 105 Durland Hall, Manhattan, KS 66506-5102, USA

Ana A. Espinel-Ingroff

Department of Medicine, Division of Infectious Diseases, Medical College of Virginia, Sanger Hall, Room 7049, 1101 E. Marshall Street, Richmond, VA 23298, USA

Stuart J. Ferguson

Department of Biochemistry, University of Oxford, South Parks Road, Oxford OX1 3QU, UK

Laura S. Frost

Department of Biological Sciences, University of Alberta, CW 405 Biological Sciences Bldg., Edmonton, Alberta T6G 2E9, Canada

Clay Fuqua

Department of Biology, 1001 E. 3rd Street, Jordan Hall 418, Indiana University Bloomington, IN 47405

Jorge Galan

Department of Microbial Pathogenesis, Yale University, New Haven, CT 06520, USA

Emil C. Gotschlich

Laboratory of Bacterial Pathogenesis and Immunology, Rockefeller University, 1230 York Avenue, New York, NY 10021-6399, USA

Peter H. Graham

Department of Soil, Water and Climate, University of Minnesota, 256 Borlaug Hall, 1991 Upper Buford Circle, St. Paul, MN 55108, USA

Carol A. Gross

Department of Microbiology, University of California, San Francisco, Medical Sciences Rm 534, #0512, 513 Parnassus Avenue, San Francisco, CA 94143-0512, USA

Lawrence Grossman

Department of Biochemistry, Johns Hopkins University School of Hygiene and Public Health, 615 N Wolfe Street, Baltimore, MD 21205-2179, USA

Janine Guespin-Michel

Laboratoire de Microbiologie du Froid, IFR CNRS – Université de Rouen, Faculté de Sciences et Techniques, Place Emile Blondel, Mont-Saint-Aignan 76821, France

Ian R. Hamilton

Department of Oral Microbiology, University of Manitoba, Faculty of Dentistry, 780 Bannatyne Avenue, Winnipeg, Manitoba R3E 0W2, Canada

Fawzy Hashem

University of Maryland, Eastern Shore, Princess Anne, Maryland, USA

J. Woodland Hastings

Department of Biology, Harvard University, Biological Laboratories, 16 Divinity Avenue, Cambridge, MA 02138-2020, USA

Jack A. Heinemann

Norwegian Institute of Gene Ecology, Tromsø, Norway

James A. Hejna

Department of Molecular and Medical Genetics, Oregon Health Sciences University, M/C L103, 3181 SW Sam Jackson Park Rd., Portland, OR 97201-3098, USA

Christophe Herman

Department of Microbiology, University of California, San Francisco, Medical Sciences Rm 534, #0512, 513 Parnassus Avenue, San Francisco, CA 94143-0512, USA

David L. Heymann

Executive Director, Communicable Diseases, World Health Organization, Geneva 27 CH-1211, Switzerland

Susan K. Hoiseth

Wyeth Vaccines Research, Pearl River, New York, USA

Joachim-V. Höltje

Max-Planck-Institut für Entwicklungsbiologie, Abteilung Biochemie, Spemannstrasse 35, Tübingen D-72076, Germany

Joseph B. Hughes

Energy and Environmental Systems Institute, Rice University, 6100 S. Main, MS-316, Houston, TX 77005, USA

Scott James Hultgren

Department of Molecular Microbiology, Washington University School of Medicine, Campus Box 8230, 660 S Euclid Avenue, 8230, St. Louis, MO 63110-1010, USA

Francoise Joset

Laboratoire de Chimie Bactérienne,
CNRS 13412 Marseille, France

Robert J. Kadner

Department of Microbiology, University
of Virginia School of Medicine, Box 441,
Health Sciences Center, Charlottesville,
VA 22908, USA

Isao Karube

School of Bionics, Tokyo University of Technology,
1404-1 Katakura-cho, Hachioji,
Tokyo 192-0982, Japan

Dennis L. Kasper

Channing Laboratory, Harvard Medical School,
181 Longwood Avenue, Boston,
MA 02115-5899, USA

Michael J. Klug

Department of Microbiology, Michigan State
University, W.K. Kellogg Biological Station, 3700
East Gull Lake Drive, Hickory Corners,
MI 49060, USA

Roger Knowles

Department of Natural Resource Sciences,
McGill University, MacDonald Campus, 21,111
Lakeshore Road, Ste-Anne de-Bellevue, Quebec,
Canada H9X 3V9

L. David Kuykendall

Agricultural Research Service, Beltsville, US
Department of Agriculture, Bldg. 011A, Barc West
Rm. 252, Plant Molecular Pathology Laboratory, PSI,
Beltsville, MD 20705, USA

Hilary M. Lappin-Scott

Hatherly Labs, University of Exeter, Exeter,
Prince of Wales Road, Devon EX4 4PS, UK

Piet Lens

Department of Environmental Technology,
Wageningen Agricultural University, P.O. Box 8129,
Wageningen 6700 EV, The Netherlands

Charles R. Lovell

Department of Biological Sciences, University of
South Carolina, Coker Life Sciences 408, Columbia,
SC 29208, USA

K. Brooks Low

Department of Therapeutic Radiology, Yale
University, Hunter Radiation Therapy, M353, 333
Cedar Street, New Haven, CT 06520, USA

Millicent Masters

Institute of Cell & Molecular Biology, University of
Edinburgh, Darwin Bldg. King's Buildings,
Mayfield Road, Edinburgh EH9 3JR, UK

A. C. Matin

Department of Microbiology and Immunology,
Stanford University, Sherman Fairchild Science
Bldg. D317, Stanford, CA 94305-5402, USA

Peter A. Meacock

Department of Genetics, University of Leicester,
Adrian Building, University Road,
Leicester LE1 7RH, UK

Ian R. McDonald

Department of Biological Sciences, University of
Warwick, Coventry CV4 7AL, UK

Paul Messner

Center for Ultrastructure Research and Institute
for Molecular Nanotechnology, University of
Agricultural Sciences, Vienna, Gregor-Mendel-Str.
33, Vienna A-1180, Austria

Linda A. Miller

Department of Automicrobial Profiling/
Clinical Microbiology, SmithKline Beecham
Pharmaceuticals, P.O. Box 5089, 1250 S.
Collegeville Rd., Mail Code UP1340,
Collegeville, PA 19426-0989, USA

Saroj K. Mishra

Division of Life Sciences, NASA/Johnson Space
Center, Houston, 3600 Bay Area Blvd.,
Houston, TX 77058, USA

Luc Montagnier

Institut Pasteur, 25-28 rue du Dr Roux,
75015 Paris, France and Department of Biology,
Queens College, NY 11367, USA

Stephen S. Morse

DARPA – Defense Advanced Research Project
Agency, Columbia University, 3701 N Fairfax Drive,
Room 838, Arlington, VA 22203-1714, USA

Robb E. Moses

Department of Molecular and Medical Genetics,
Oregon Health Sciences University,
M/C L103, 3181 SW Sam Jackson Park Rd.,
Portland, OR 97201-3098, USA

Matthew A. Mulvey

Department of Molecular Microbiology,
Washington University School of Medicine,
Campus Box 8230, 660 S Euclid Avenue, 8230,
St. Louis, MO 63110-1010, USA

Noreen E. Murray

Institute of Cell and Molecular Biology,
University of Edinburgh, King's Buildings,
Mayfield Road, Edinburgh, EH9 3JR, UK

J. Colin Murrell

Preface

The field of Microbiology encompasses highly diverse life forms—bacteria, archaea, fungi, protists, and viruses. They have a profound influence on all life on Earth: they play an essential role in the cycles of matter in nature, affect all biological environments, interact in countless ways with other living beings, and play a crucial role in agriculture and industry. The literature associated with Microbiology, of necessity, tends to be specialized and focused. For that reason, it is difficult to find sources that provide a broad perspective on a wide range of microbiological topics. That is the aim of *The Desk Encyclopedia of Microbiology*.

The concept behind this venture is to provide a single reference volume with appeal to microbiologists on all levels and fields, including those working in research, teaching, industry, and government. We believe that this book will be helpful, especially for accessing material in areas in which the reader is not a specialist. It is intended to facilitate preparing lectures,

grant applications and reports, and to satisfy curiosity regarding microbiological topics.

The Desk Encyclopedia of Microbiology is principally a synthesis from the comprehensive and multivolumed *Encyclopedia of Microbiology*. Our intention is to provide affordable and ready access to a large variety of topics within one set of covers. To this end we have chosen subjects that, in our opinion, will be of greatest interest to the largest number of readers. Included are the most general chapters from *The Encyclopedia of Microbiology*, brought up to date and augmented with current references and related URLs. We have emphasized topics that are currently “hot” in the field of Microbiology, including additional chapters from other sources.

The result is a volume where coverage is extensive but not overly long in specific details. We believe this will be a most appropriate reference for anyone with an interest in the intriguing field of Microbiology.

Washington University School of Medicine

GLOSSARY

adhesin A molecule, typically a protein, that mediates bacterial attachment by interacting with specific receptors.

extracellular matrix A complex network of proteins and polysaccharides secreted by eukaryotic cells. Functions as a structural element in tissues, in addition to modulating tissue development and physiology.

invasin An adhesin that can mediate bacterial invasion into host eukaryotic cells.

isoreceptors Eukaryotic cell membrane components which contain identical receptor determinants recognized by a bacterial adhesin.

lectins Proteins that bind carbohydrate motifs.

Adhesion is a principal step in the colonization of inanimate surfaces and living tissues by bacteria. It is estimated that the majority of bacterial populations in nature live and multiply attached to a substratum. Bacteria have evolved numerous, and often redundant, mechanisms to facilitate their adherence to other organisms and surfaces within their environment. A vast number of structurally and functionally diverse bacterial adhesive molecules, called adhesins, have been identified. The adhesins expressed by different bacterial species can directly influence bacterial tropism and mediate molecular crosstalk among organisms.

I. MECHANISMS OF BACTERIAL ADHESION

Bacterial adhesion to living cells and to inanimate surfaces is governed by nonspecific electrostatic and hydrophobic interactions and by more specific adhesin–receptor binding events. Studies of bacterial adherence indicate that initial bacterial interactions with a surface are governed by long-range forces, primarily van der Waals and electrostatic interactions. The surface of most gram-negative and many gram-positive bacteria is negatively charged. Thus, bacteria will often readily adhere nonspecifically to positively charged surfaces. In some cases, bacterial proteins possessing hydrophobic surfaces, including many adhesins, can also mediate nonspecific bacterial interactions with exposed host cell membrane lipids and with other hydrophobic surfaces encountered in nature. If the approach of bacteria to a surface, such as a negatively charged host cell membrane, is unfavorable, bacteria must overcome an energy barrier to establish contact. Protein–ligand binding events mediated by bacterial adhesins can often overcome or bypass repulsive forces and promote specific and intimate microbial interactions with host tissues and other surfaces.

Bacteria can produce a multitude of different adhesins, usually proteins, with varying specificities for a wide range of receptor molecules. Adhesins are presented on bacterial surfaces as components of

filamentous, nonflagellar structures, known as pili or fimbriae, or as afimbrial (or nonfimbrial) monomeric or multimeric proteins anchored within the bacterial membrane. Other nonprotein components of bacterial membranes, including lipopolysaccharides (LPS) synthesized by gram-negative bacteria, and lipoteichoic acid in some gram-positive bacteria, can also function as adhesive molecules. Adhesins are often only minor subunits intercalated within pilus rods or located at the distal tips of pili, but they can also constitute the major structural subunits of adhesive pili. The molecular machinery required for the synthesis of many different adhesive pili and afimbrial adhesins is conserved, although the receptor specificities of the different adhesins can vary widely. Many bacterial adhesins function as lectins, mediating bacterial interactions with carbohydrate moieties on glycoproteins or glycolipids. Other adhesins mediate direct contact with specific amino acid motifs present in receptor proteins. Plant and animal cell surfaces present a large array of membrane proteins, glycoproteins, glycolipids, and other components that can potentially serve as receptors for bacterial adhesins. Protein constituents of the extracellular matrix (ECM) are also often used as bacterial receptors. In some cases, ECM proteins can function as bridges, linking bacterial and host eukaryotic cells. In addition, organic and inorganic material that coats inanimate surfaces, such as medical implants, pipes, and rocks, can act as receptors for bacterial adhesins, allowing for the establishment of microbial communities or biofilms. Adhesins also mediate interbacterial associations, facilitating the transfer of genetic material between bacteria and promoting the coaggregation of bacterial species in sites such as the oral cavity.

A single bacterium can often express multiple adhesins with varying receptor specificities. These adhesins can function synergistically and, thus, enhance bacterial adherence. Alternately, adhesins may be regulated and expressed differentially, allowing bacteria to alter their adhesive repertoire as they enter different environmental situations. To date, a large number of bacterial adhesins have been described, but relatively few receptors have been conclusively identified. Bacterial adhesins can show exquisite specificity and are able to distinguish between very closely related receptor structures. The ability of bacterial adhesins to recognize specific receptor molecules is dependent upon the three-dimensional architecture of the receptor in addition to its accessibility and spatial orientation. Most studies to date of bacterial adhesion have focused on host-pathogen interactions. Numerous investigations have indicated that bacterial adhesion is an essential

step in the successful colonization of host tissues and the production of disease by bacterial pathogens. Examples of adhesins expressed by bacterial pathogens and their known receptors are presented in Table 1.1. To illustrate some of the key concepts of bacterial adhesion, the modes of adhesion of a few well-characterized pathogens are discussed in the following sections.

A. Adhesins of uropathogenic *Escherichia coli*

Uropathogenic strains of *E. coli* are the primary causative agents of urinary tract infections among humans. These bacteria can express two of the best characterized adhesive structures, P and type 1 pili. These pili are composite organelles, consisting of a thin fibrillar tip structure joined end-to-end to a right-handed helical rod. Chromosomally located gene clusters, that are organizationally as well as functionally homologous, encode P and type 1 pili. The P pilus tip fibrillum contains a distally located adhesin, PapG, in association with three other tip subunits, PapE, PapF, and PapK. The adhesive tip fibrillum is attached to the distal end of a thicker pilus rod composed of repeating PapA subunits. An additional subunit, PapH, anchors the PapA rod to the outer membrane.

The P pilus PapG adhesin binds to the α -D-galactopyranosyl-(1-4)- β -D-galactopyranoside (Gal α (1-4)Gal) moiety present in the globoseries of glycolipids, which are expressed by erythrocytes and host cells present in the kidney. Consistent with this binding specificity, P pili have been shown to be major virulence factors associated with pyelonephritis caused by uropathogenic *E. coli*. Three distinct variants of the PapG adhesin (G-I, G-II, and G-III) have been identified that recognize three different Gal α (1-4)Gal-containing isoreceptors: globotriaosylceramide, globotetraosylceramide (globoside), and globopentaosylceramide (the Forssman antigen). The different PapG adhesins significantly affect the tropism of pyelonephritic *E. coli*. For example, urinary tract *E. coli* isolates from dogs often encode the G-III adhesin that recognizes the Forssman antigen, the dominant Gal α (1-4)Gal-containing isoreceptor in the dog kidney. In contrast, the majority of urinary tract isolates from humans express the G-II adhesin that preferentially recognizes globoside, the primary Gal α (1-4)Gal-containing isoreceptor in the human kidney.

In comparison with P pili, type 1 pili are more widely distributed and are encoded by more than 95% of all *E. coli* isolates, including uropathogenic and

TABLE 1.1 Selected examples of bacterial adhesins and their receptors

Organism	Adhesin	Receptor	Form of receptor ^a	Associated disease(s)
<i>Escherichia coli</i>	P pili (PapG)	Gal α (1–4)Gal	GL	Pyelonephritis/cystitis
	Type 1 pili (FimH)	D-mannose (uropalakin 1a and 1b, CD11, CD18, uromodulin)	GP	Cystitis
	Curli (CsgA)	Fibronectin/laminin/ plasminogen	ECM	Sepsis

commensal intestinal strains. The type 1 pilus tip fibrillum is comprised of two subunits, FimF and FimG, in addition to the adhesin, FimH. The adhesive tip is connected to the distal end of a thicker pilus rod composed of repeating FimA subunits. In addition to its localization within the pilus tip, the FimH adhesin also appears to be occasionally intercalated along the length of the type 1 pilus rod. FimH binds to mannose containing host receptors expressed by a wide variety of host cell types and has been shown to be a significant virulence determinant for the development of bladder infections. Natural phenotypic variants of the FimH adhesin have been identified by Sokurenko *et al.* (1998), which differentially bind to mono-mannose structures. Interestingly, most uropathogenic isolates express FimH variants that bind well to mono-mannose residues, whereas most isolates from the large intestine of healthy humans express FimH variants that interact poorly with mono-mannose structures. Mono-mannose residues are abundant in the oligosaccharide moieties of host proteins, known as uroplakins, that coat the luminal surface of the bladder epithelium. *In vitro* binding assays by Wu *et al.* (1996) have demonstrated that type 1-piliated *E. coli* can specifically bind two of the uroplakins, UP1a and UP1b. Scanning and high-resolution electron microscopy have shown that type 1 pili can mediate direct and intimate bacterial contact with the uroplakin-coated bladder epithelium (Fig. 1.1).

The assembly of P pili and type 1 pili requires two specialized assembly proteins: a periplasmic chaperone and an outer membrane usher. Periplasmic chaperones facilitate the import of pilus subunits across the inner membrane and mediate their delivery to outer membrane usher complexes, where subunits are assembled into pili. Homologous chaperone/usher pathways modulate the assembly of over 30 different adhesive organelles, expressed by uropathogenic *E. coli* and many other gram-negative pathogens. Among the adhesive structures assembled via a chaperone/usher pathway by uropathogenic *E. coli* are S pili, nonfimbrial adhesin I, and members of the Dr adhesin family. This family includes the uropathogenic-associated afimbrial adhesins AFA-I and AFA-III and the fimbrial adhesin Dr, in addition to the diarrhea-associated fimbrial adhesin F1845. These adhesins recognize the Dr^a blood group antigen present on decay accelerating factor (DAF), a complement regulatory factor expressed on erythrocytes and other tissues, including the uroepithelium. These four members of the Dr adhesin family appear to recognize different epitopes of the Dr^a antigen. The Dr adhesin, but not the other three, also recognizes type IV collagen. Members of the Dr adhesin family

are proposed to facilitate ascending colonization and chronic interstitial infection of the urinary tract. It is unclear why the Dr and F1845 adhesins assemble into fimbria while AFA-I and AFA-III are assembled as nonfimbrial adhesins on the bacterial surface. It has been suggested that afimbrial adhesins, such as AFA-I and AFA-III, are derived from related fimbrial adhesins, but have been altered such that the structural attributes required for polymerization into a pilus are missing while the adhesin domain remains functional and anchored on the bacterial surface.

B. Neisserial adhesins

Neisseria gonorrhoeae and *N. meningitidis* are exclusively human pathogens that have developed several adhesive mechanisms to colonize mucosal surfaces. Initial contact with mucosal epithelia by *Neisseria* species is mediated by type 4a pili. These adhesive organelles are related to a group of multifunctional structures expressed by a wide diversity of bacterial species, including *Pseudomonas aeruginosa*, *Moraxella* species, *Dichelobacter nodus*, and others. Type-4a pili are assembled by a type II secretion system that is distinct from the chaperone/usher pathway. They are comprised primarily of a small subunit, pilin, that is packaged into a helical arrangement within pili. The type 4a pilin can mediate bacterial adherence, but in *Neisseria* species, a separate, minor tip protein, PilC, has also been implicated as an adhesin. A eukaryotic membrane protein, CD46, is proposed to be a host receptor for type 4a pili expressed by *N. gonorrhoeae*, although it is currently unclear which pilus component binds this host molecule.

Following primary attachment mediated by type-4a pili, more intimate contact with mucosal surfaces is apparently established by the colony opacity-associated (Opa) proteins of *Neisseria* species. These proteins constitute a family of closely related but size-variable outer membrane proteins that are expressed in a phase variable fashion. Opa proteins mediate not only adherence, but they also modulate bacterial invasion into host cells. A single neisserial strain can encode from 3 to 11 distinct Opa variants, with each Opa protein being expressed alternately of the others. The differential expression of Opa variants can alter bacterial antigenicity and possibly modify bacterial tropism for different receptors and host cell types. Some Opa variants recognize carbohydrate moieties of cell surface-associated heparin sulfate proteoglycans (HSPGs), which are common constituents of mammalian cell membranes. The majority of Opa variants, however, bind via protein-protein interactions to CD66 transmembrane glycoproteins, which comprise

FIGURE 1.1 Type 1 pilus-mediated bacterial adherence to the mouse bladder epithelium was visualized by (A and B) scanning and (C–H) high-resolution freeze–fracture, deep-etch electron microscopy. Mice were infected via transurethral inoculation with type 1-piliated uropathogenic *E. coli*. Bladders were collected and processed for microscopy at 2 h. after infection. Bacteria adhered randomly across the bladder luminal surface, both singly and in large, biofilmlike microcolonies, some of which contained several hundred bacteria (A and B). The type 1 pili-mediating bacterial adherence were resolved by high-resolution electron microscopy techniques. The adhesive tips of type 1 pili make direct contact with the uroplakin-coated surface of the bladder epithelium (D–G). Hexagonal arrays of uroplakin complexes are visible. The boxed areas in (C) and (D) are shown magnified, respectively, in (D) and (E). In (H), type 1 pili span from the host cell membrane on the right to the bacterium on the left. These images demonstrate that type 1 pili can mediate intimate bacterial attachment to host bladder epithelial cells. Scale bars indicate 5 μm (A and B), 0.5 μm (C and F), and 0.1 μm (D, E, G, H) (Plate 1). (Reprinted with permission from Mulvey, M. A., *et al.* (1998). Induction and evasion of host defenses by type 1-piliated uropathogenic *Escherichia coli*. *Science* **282**, 1494–1497. Copyright 1998 American Association for the Advancement of Science.)

a subset of the carcinoembryonic antigen (CEA) receptor family of the immunoglobulin super-family. Individual Opa variants specifically recognize distinct CD66 receptors and this likely influences both the tissue tropism of *Neisseria* and the host cell responses to neisserial attachment. In addition to pili and Opa proteins, the lipopolysaccharide (lipooligosaccharide, LOS) and a distinct outer membrane protein, Opc, expressed by *Neisseria* can also influence bacterial adhesion and invasion. Deconvoluting the various roles of the different adhesive components of *Neisseria* during the infection process remains a major challenge.

C. Adhesins of *Haemophilus influenzae*

Haemophilus influenzae is a common pathogen of the human respiratory tract. Isolates of *H. influenzae* can be divided into encapsulated and nonencapsulated, or nontypable, forms. Prior to the use of *H. influenzae* conjugate vaccines, capsulated strains of *H. influenzae* were the primary cause of childhood bacterial meningitis and a major cause of other bacteremic diseases in children. Vaccines effective against nontypable strains have not yet been developed and these strains remain important human pathogens, causing pneumonia, otitis media, sinusitis, and bronchitis. Several

adhesins have been identified which facilitate the colonization of the respiratory epithelium by both encapsulated and nontypable *H. influenzae*.

During the initial stages of the infection process, nontypable *H. influenzae* associates with respiratory mucus, apparently through interactions between bacterial outer membrane proteins (OMPs P2 and P5) and sialic acid-containing oligosaccharides within the mucus. Both nontypable and encapsulated strains of *H. influenzae* can initiate direct contact with the respiratory epithelium via adhesive pili. Over 14 serological types of adhesive pili have been indentified in *H. influenzae*. These pili are composite structures assembled by chaperone/usher pathways similar to those used by uropathogenic *E. coli* to assemble P and type 1 pili. Piliated strains of *H. influenzae* preferentially bind to nonciliated cells or damaged epithelium. The pili of *H. influenzae* can recognize the AnWj antigen, in addition to gangliosides and other compounds containing siallyllactoceramide. Following initial attachment mediated by pili, the polysaccharide capsule of encapsulated strains is reduced, enabling a second adhesin, Hsf, to establish more intimate bacterial contact with host epithelial cells. Hsf assembles into short, thin fibrils on the bacterial surface. While Hsf expression is restricted to encapsulated strains of *H. influenzae*, a subpopulation of nontypable strains expresses a Hsf homolog called Hia. Both Hsf and Hia share homology with other bacterial adhesins including AIDA-1, an adherence factor produced by diarrheagenic *E. coli*.

Instead of adhesive pili and Hia, the majority of nontypable *H. influenzae* isolates produce two alternate adhesins: high molecular weight surface-exposed proteins called HMW1 and HMW2. These two adhesins share significant sequence identity with each other and are similar to filamentous hemagglutinin (FHA), an adhesin and colonization factor expressed by *Bordetella pertussis*. HMW1 and HMW2 have distinct adhesive specificities and may function at different steps in the infection process. The receptors for the HMW adhesins appear to be negatively charged glycoconjugates that have not yet been completely defined. Nontypable *H. influenzae* encodes several other adhesive factors, including two Hsp-70-related proteins, which can mediate bacterial binding to sulfoglycolipids. Interestingly, other heat shock proteins have been implicated in the adherence of other microbial pathogens including *Helicobacter pylori*, *Mycoplasma*, and *Chlamydia trachomatis*.

Work by St. Geme and coworkers (1998) has highlighted an additional adhesin, Hap, which is expressed by virtually all nontypable *H. influenzae* isolates. Hap mediates low-level adherence to epithelial

cells, complementing the binding activities of pili and Hia or HMW1 and HMW2. Hap also promotes inter-bacterial associations leading to bacterial aggregation and microcolony formation on the epithelial surface. The mature Hap adhesin consists of a C-terminal outer membrane protein domain, designated Hap_β, and a larger extracellular domain designated Hap_α. The Hap_α domain, which is responsible for mediating adherence, has serine protease activity and can be autoproteolytically cleaved, releasing itself from the bacterial surface. Interestingly, secretory leukocyte protease inhibitor (SLPI), a natural host component of respiratory-tract secretions, which possibly protects the respiratory epithelium from proteolytic damage during acute inflammation, has been shown to inhibit Hap autoproteolysis and enhance bacterial adherence. Despite the presence of SLPI, Hap_α-mediated adherence *in vivo* is likely transient. Over time, the eventual autoproteolysis and release of the Hap_α adhesin domain from the bacterial surface may allow bacterial spread from microcolonies on the respiratory epithelium and aid the bacteria in evading the host immune response. Identification of the receptor molecules recognized by Hap awaits further studies.

D. Adherence to components of the extracellular matrix

One of the principal functions of the ECM is to serve as substrate for the adherence of eukaryotic cells within animal tissues. The ECM is composed of polysaccharides and numerous proteins including fibronectin, vitronectin, laminin, elastin, collagen, fibrinogen, tenascin, entactin, and others. Thin flexible mats of specialized ECM, known as basal laminae or basement membranes, underlie all epithelial cells and surround individual fat cells, muscle cells, and Schwann cells. Binding of ECM proteins is one of the primary mechanisms used by many pathogenic bacteria to adhere to host tissues. Bacterial adhesins have been identified which recognize specific components of the ECM and a few adhesins, such as the Opa₅₀ protein of *Neisseria* and the YadA adhesin of *Yersinia enterocolitica*, are able to recognize multiple ECM components. Some bacterial adhesins preferentially recognize immobilized, cell-bound ECM components over soluble forms. The YadA adhesin expressed by *Y. enterocolitica*, for example, mediates adherence to cell-bound fibronectin, but not to soluble fibronectin within plasma. This may allow *Y. enterocolitica* to more efficiently bind tissue rather than circulating molecules.

The tissue distribution of ECM components can directly influence the tropism of a bacterial pathogen.

For example, *Mycobacterium leprae*, the causative agent of leprosy, binds LN-2, an isoform of the ECM component laminin. This ECM component recognizes a host cell-surface receptor, α -dystroglycan, and serves as a bridge linking host and bacterial cells. *M. leprae* targets the Schwann cells of the peripheral nervous system and can also invade the placenta and striated muscle of leprosy patients. The tissue distribution of LN-2, which is restricted to the basal laminae of Schwann cells, striated muscles, and trophoblasts of the placenta, directly correlates with sites of natural infection by *M. leprae*.

In contrast to the restricted tissue distribution of LN-2, most components of the ECM are more widely apportioned and can interact with receptor molecules expressed by a broad range of cell types present within a variety of different tissues. By interacting with widely distributed components of the ECM, bacteria greatly enhance their adhesive potential. Numerous bacteria are able to bind fibronectin, an ECM component present in most tissues and body fluids and a prominent constituent of wounds. The bacterial adhesins that bind fibronectin are diverse. For example, *E. coli* and *Salmonella* species express thin, irregular, and highly aggregated surface fibers, known as curli, that bind fibronectin in addition to other receptor molecules. *Mycobacterium* species produce at least five fibronectin-binding molecules, three of which are related and collectively known as the BCG85 complex. *Streptococcus* expresses an even larger number of different fibronectin-binding adhesins, including ZOP, lipoteichoic acid, GAPDH, FBP54, M protein, and several related molecules represented by Protein F. Binding of Protein F and related adhesins to fibronectin is specific and essentially irreversible. Members of the Protein F family of adhesins have similar domain architectures, although they appear to interact with fibronectin differently. Protein F possesses two distinct domains, composed of repeated sequence motifs, which bind independently of each other to different sites at the N-terminus of fibronectin. Additional fibronectin-binding proteins related to the Protein F family of adhesins have also been identified in *Staphylococcus*. These gram-positive bacteria, in addition to producing fibronectin-binding proteins, can also express an array of other adhesive molecules, which bind other widely distributed ECM components, including collagen, fibrinogen, and elastin. By encoding a large repertoire of adhesins able to recognize ECM components, *Streptococcus*, *Staphylococcus*, and other pathogens, presumably, increase their capacity to effectively bind and colonize sites within host tissues.

II. CONSEQUENCES OF BACTERIAL ADHESION

Research in recent years has demonstrated that interactions between bacterial adhesins and receptor molecules can act as trigger mechanisms, activating signal transduction cascades and altering gene expression in both bacterial and host cells. Zhang and Normark showed in 1996 that the binding of host cell receptors by P pili activated the transcription of a sensor-regulator protein, AirS, which regulates the bacterial iron acquisition system of uropathogenic *E. coli*. This response may enable uropathogens to more efficiently obtain iron and survive in the iron-poor environment of the urinary tract. Around the same time, Wolf-Watz and colleagues showed, using *Y. pseudotuberculosis*, that bacterial contact with host cells could increase the rate of transcription of virulence determinants called Yop effector proteins. More recently, Taha and coworkers (1998) demonstrated that transcription of the PilC1 adhesin of *N. meningitidis* was transiently induced by bacterial contact with host epithelial cells. The PilC1 adhesin can be incorporated into the tips of type-4a pili, but it can also remain associated with the bacterial outer membrane, where it can, presumably, facilitate pilus assembly. The up-regulation of the PilC1 adhesin may enhance bacterial adherence to host cells by promoting the localization of PilC1 into the tips of type 4a pili.

Signal transduction pathways are activated within host eukaryotic cells in response to attachment mediated by many different bacterial adhesins. For example, the binding of type-4a pili expressed by *Neisseria* to host cell receptors (presumably, CD46) can stimulate the release of Ca^{++} stores within target epithelial cells. Fluxes in intracellular Ca^{++} concentrations are known to modulate a multitude of eukaryotic cellular responses. Similarly, the binding of P pili to Gal α (1-4)Gal-containing host receptors on uroepithelial cells can induce the release of ceramides, important second messenger molecules that can influence a number of signal transduction processes. Signals induced within uroepithelial cells upon binding P-piliated bacteria result in the up-regulation and eventual secretion of several immunoregulatory cytokines. The binding of type 1-piliated and other adherent bacteria to a variety of host epithelial and immune cells has also been shown to induce the release of cytokines, although the signaling pathways involved have not yet been well defined. In some cases, bacteria may co-opt host signal transduction pathways to enhance their own attachment. For example, binding of the FHA adhesin of *B. pertussis* to a monocyte integrin receptor complex activates host signal pathways that lead to the

up-regulation of another integrin, complement receptor 3 (CR3). FHA can bind CR3 through a separate domain and, thus, enhance the adhesion of *B. pertussis*.

The activation of host signal pathways following bacterial attachment can result in dramatic rearrangements of the eukaryotic cytoskeleton, which can lead to the internalization of adherent bacteria. Many pathogenic bacteria invade host eukaryotic cells to evade immune responses or to pass through cellular barriers, such as the intestinal epithelium. In some cases, bacteria introduce effector molecules into their target host cells to trigger cytoskeletal rearrangements and intense ruffling of the host cell membrane that results in bacterial uptake. In other situations, bacterial adhesins (which are sometimes referred to as invasins) more directly mediate bacterial invasion by interacting with host cell membrane receptors that sequentially encircle and envelope the attached bacterium. This type of invasion is referred to as the "zipper" mechanism and requires the stimulation of host signaling cascades, including the activation of protein tyrosine kinases. The invasin protein of *Yersinia* and internalin expressed by *Listeria* can both mediate bacterial internalization into host cells by such a zipper mechanism by interacting with β_1 -integrin and E-cadherin, respectively. The Opa proteins of *Neisseria* can also mediate bacterial internalization into host cells by a zipperlike mechanism. Recent work by several labs has indicated that fimbrial adhesins, such as FimH within type 1 pili, can also function as invasins.

III. TARGETING ADHESINS FOR ANTIMICROBIAL THERAPY

Bacterial adhesin-receptor binding events are critical in the pathogenesis of virtually every bacterial disease. In some cases, the knockout of a specific adhesin can greatly attenuate bacterial virulence. Uropathogenic *E. coli* strains, for example, which have been engineered to express type 1 pili lacking the FimH adhesin, are unable to effectively colonize the bladder. Similarly, a P-piliated pyelonephritic strain of *E. coli* lacking a functional PapG adhesin is unable to infect the kidney. For many other bacteria, attachment is a multifaceted process involving several adhesins that may have complementing and overlapping functions and receptor specificities. In these cases, it has been more difficult to discern the roles of individual adhesins in disease processes. The construction of mutants with knockouts in more than one adhesin is beginning to shed light on the interrelationships between multiple bacterial adhesins.

The central role of bacterial adhesins at the host-pathogen interface during the infection process has made them attractive targets for the development of new antimicrobial therapies. Vaccines directed against individual adhesins and adhesive pili have had some success in the past. However, antigenic variation of the major immunodominant domains of some adhesive organelles and the immunorecessive nature of others have frustrated progress in this area. Fortunately, by unraveling the molecular details of adhesin structure and biogenesis, substantial progress is being made. For example, the identification of FimH as the adhesive subunit of type 1 pili and the elucidation of the chaperone/usher pathway used to assemble these adhesive organelles has made it possible to purify large quantities of native FimH and to test its efficacy as a vaccine. Unlike the major type 1 pilus subunit, FimA, there is relatively little heterogeneity among the FimH adhesins expressed by diverse *E. coli* strains. The use of purified FimH as a vaccine, rather than whole type 1 pili in which FimH is present only in low numbers, has proven to significantly enhance the host immune response against the FimH adhesin. In early trials, FimH-vaccinated animals showed substantial resistance to infection by a wide variety type 1-piliated uropathogenic *E. coli* strains.

In addition to the prophylactic approach of generating vaccines to inhibit bacterial adhesion, other anti-adhesin strategies are being explored. With increased knowledge of the mechanisms used to assemble adhesins on the bacterial surface, it may be possible to design specific inhibitors of adhesin biogenesis. For example, synthetic compounds that specifically bind and inactivate periplasmic chaperones could potentially inhibit the biogenesis of a wide range of bacterial adhesive organelles. The use of soluble synthetic receptor analogs that bind bacterial adhesins substantially better than the natural monomeric ligands represents an additional strategy for inhibiting bacterial attachment and colonization. Recent advances in the synthesis of multimeric carbohydrate polymers have highlighted the possibility of creating high affinity receptor analogs that could potentially work at pharmacological concentrations within patients. Such compounds could also be used to competitively remove adherent bacteria from medical implants, industrial pipes, and other surfaces. Furthermore, it may be possible to inhibit multiple bacterial adhesins with a single compound by incorporating several receptor analogs within a single carbohydrate polymer. Continued research into the structure, function, and biogenesis of bacterial adhesins promises not only to enhance our knowledge

of pathogenic processes, but may also help augment our current arsenal of antimicrobial agents.

Agrobacterium and plant cell transformation

Peter J. Christie

University of Texas Health Science Center at Houston

GLOSSARY

autoinducer An acyl homoserine lactone secreted from bacteria which, under conditions of high cell density, passively diffuses across the bacterial envelope and activates transcription.

border sequences 25-bp direct, imperfect repeats that delineate the boundaries of T-DNA.

conjugal pilus An extracellular filament encoded by a conjugative plasmid involved in establishing contact between plasmid-carrying donor cells and recipient cells.

conjugation Transfer of DNA between bacteria by a process requiring cell-to-cell contact.

mobilizable plasmid Conjugal plasmid that carries an origin of transfer (*oriT*) but lacks genes coding for its own transfer across the bacterial envelope.

T-DNA Segment of the *Agrobacterium* genome transferred to plant cells.

transconjugant A cell that has received a plasmid from another cell as a result of conjugation.

transfer intermediate A nucleoprotein particle composed of a single strand of the DNA destined for export and one or more proteins that facilitate DNA delivery to recipient cells.

type IV transporters A conserved family of macromolecular transporters evolved from ancestral conjugation systems for the purpose of exporting DNA or protein virulence factors between prokaryotic cells or to eukaryotic hosts.

Agrobacterium tumefaciens is a gramnegative soil bacterium with the unique ability to infect plants through a process that involves delivery of a specific segment of its genome to the nuclei of susceptible plant cells. The transferred DNA (T-DNA) is a discrete region of the bacterial genome defined by directly repeated border sequences. The T-DNA is important for infection because it codes for genes which, when expressed in the plant cell, disrupt plant cell growth and division events.

Approximately 20 years ago, it was discovered that oncogenic DNA could be excised from the T-DNA and in its place virtually any gene of interest could be inserted. *Agrobacterium tumefaciens* could then efficiently deliver the engineered T-DNA to a wide array of plant species and cell types. Transformed plant cells could be selected by cotransfer of an antibiotic resistance marker and regenerated into fertile, transgenic plants. The discovery that *A. tumefaciens* is a natural and efficient DNA delivery vector for transforming plants is largely responsible for the burgeoning industry of plant genetic engineering, which today has many diverse goals ranging from crop improvement to the use of plants as "pharmaceutical factories" for high-level production of biomedically important proteins.

Because of the dual importance of *Agrobacterium* as a plant pathogen and as a DNA delivery system, an extensive literature has emerged describing numerous aspects of the infection process and the myriad of ways this organism has been exploited for plant genetic

engineering. The aim of this article is to summarize recent advances in our knowledge of this system, with particular emphasis on chemical signaling events, the T-DNA processing and transport reactions, and exciting novel applications of *Agrobacterium*-mediated gene delivery to eukaryotic cells.

I. OVERVIEW OF INFECTION PROCESS

Agrobacterium species are commonly found in a variety of environments including cultivated and non-agricultural soils, plant roots, and even plant vascular systems. Despite the ubiquity of *Agrobacterium* species in soil and plant environments, only a small percentage of isolates are pathogenic. Two species are known to infect plants by delivering DNA to susceptible plant cells. *Agrobacterium tumefaciens* is the causative agent of crown gall disease, a neoplastic disease characterized by uncontrolled cell proliferation and formation of unorganized tumors. *Agrobacterium rhizogenes* induces formation of hypertrophies with a hairy root appearance referred to as "hairy root" disease. The pathogenic strains of both species possess large plasmids that encode most of the genetic information required for DNA transfer to susceptible plant cells. The basic infection process is similar for both species, although the gene composition of the transferred DNA

(T-DNA) differs, and therefore, so does the outcome of the infection. This article focuses on recent advances in our understanding of the *A. tumefaciens* infection process.

The basic infection cycle can be described as follows (Fig. 2.1). Pathogenic *A. tumefaciens* strains carry large, ~180-kb tumor-inducing (Ti) plasmids. The Ti plasmid harbors the T-DNA and virulence (*vir*) genes involved in T-DNA delivery to susceptible plant cells. As with many bacterial pathogens of plants and mammals, *A. tumefaciens* infects only at wound sites. As part of the plant wound response, various plant cell wall precursors, including defined classes of phenolic compounds and monosaccharide sugars, are released into the extracellular milieu. These molecules play an important role in the infection process as inducers of the *vir* genes. On *vir* gene activation, T-DNA is processed into a nucleoprotein particle termed the T-complex. The T-complex contains information for (i) export across the *A. tumefaciens* cell envelope via a dedicated transport system, (ii) movement through the plant plasma membrane and cytosol, (iii) delivery to the plant nuclear pore, and (iv) integration into the plant genome. Once integrated into the plant genome, T-DNA genes are expressed and the resulting gene products ultimately disrupt the balance of two endogenous plant hormones that synergistically coordinate plant cell growth and division events. The imbalance of these hormones contributes to loss of cell growth control

FIGURE 2.1 Overview of the *Agrobacterium tumefaciens* infection process. Upon activation of the VirA/VirG two-component signal transduction system by signals released from wounded plant cells, a single strand of T-DNA is processed from the Ti plasmid and delivered as a nucleoprotein complex (T-complex) to plant nuclei. Expression of T-DNA genes in the plant results in loss of cell growth control and tumor formation (see text for details).

A. tumefaciens strains that are present in the vicinity of the tumor.

B. Opine catabolism

The regions of two Ti plasmids coding for opine catabolism have been sequenced and shown to code for three functions related to opine catabolism (Fig. 2.2). The first is a regulatory function that controls expression of the opine transport and catabolism genes. The regulatory protein is OccR for the octopine catabolism region of plasmid pTiA6. Recent studies have shown that OccR positively regulates expression of the *occ* genes involved in octopine uptake and catabolism by inducing a bend in the DNA at the OccR binding site. Interestingly, octopine alters both the affinity of OccR for its target site and the angle of the DNA bend, suggesting that octopine modulates OccR regulatory activity. The regulatory protein is AccR for the nopaline catabolism region of plasmid pTiC58. In contrast to OccR, AccR functions as a negative regulator of *acc* genes involved in nopaline catabolism.

The second and third functions, opine transport and catabolism, are encoded by several genes that are transcribed from a single promoter. At the proximal end of the operon is a set of genes that code for one or more transport systems conferring opine-specific binding and uptake. Typically, one or more of these genes encode proteins homologous to energy-coupling proteins found associated with the so-called ATP-binding cassette (ABC) superfamily of transporters. The ABC transporters

are ubiquitous among bacterial and eukaryotic cells, and they provide a wide variety of transport functions utilizing the energy of ATP hydrolysis to drive the transport reaction. At the distal end of the operon are genes involved in cleaving the opiens to their parent compounds for use as carbon and nitrogen sources for the bacterium.

C. Ti plasmid conjugation

The Ti plasmid transfer (*tra* and *trb*) functions direct the conjugal transmission of the Ti plasmid to bacterial recipient cells. The transfer genes of conjugative plasmids code for DNA processing and transport system that assembles at the bacterial envelope for the purpose of delivering conjugal DNA transfer intermediates to recipient cells. DNA sequence studies have shown that one set of transfer genes codes for many proteins that are related to components of other plasmid and protein toxin transport systems. As described later in more detail, this evolutionarily conserved family of transporters is referred to as a type IV secretion system.

1. Autoinduction-dependent Ti plasmid transfer

Recent work has demonstrated that a regulatory cascade exists to activate Ti plasmid transfer under conditions of high cell density (Fig. 2.3). This regulatory cascade initiates when *A. tumefaciens* imports opiens released from plant cells. For the octopine pTiA6 plasmid, OccR acts in conjunction with octopine to activate transcription of the *occ* operon. Although the

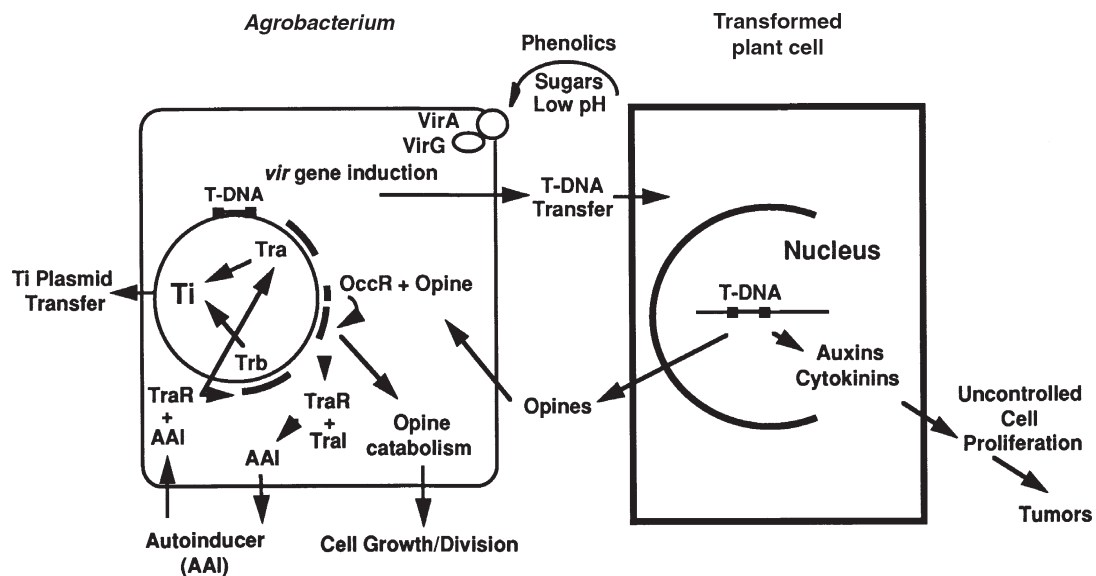

FIGURE 2.3 A schematic of chemical signaling events between *Agrobacterium* and the transformed plant cell. Signals released from wounded plant cells initiate the infection process leading to tumor formation. Opiens released from wounded plant cells activate opine catabolism functions for growth of infecting bacteria. Opiens also activate synthesis of *TraR* for autoinducer (AAI) synthesis. *TraR* and AAI at a critical concentration activate the Ti plasmid conjugation functions (see text for details).

majority of the *occ* operon codes for octopine transport and catabolism functions, the distal end of the *occR* operon encodes a gene for a transcriptional activator termed TraR. TraR is related to LuxR, an activator shown nearly 20 years ago to regulate synthesis of an acyl homoserine lactone termed autoinducer. Cells that synthesize autoinducer molecules secrete these molecules into the environment. At low cell densities, autoinducer is in low concentration, whereas at high cell densities this substance accumulates in the surrounding environment and passively diffuses back into the bacterial cell to activate transcription of a defined set of genes. In the case of *A. tumefaciens*, the autoinducer is an *N*-3-(oxo-octonoyl)-L-homoserine lactone termed *Agrobacterium* autoinducer (AAI). AAI acts in conjunction with TraR to activate transcription of the Ti plasmid *tra* genes and *traI*, whose product mediates synthesis of AAI. Therefore, synthesis of TraR under conditions of high cell density creates a positive-feedback loop whereby a TraR–AAI complex induces transcription of TraI, which in turn results in enhanced synthesis of more AAI. It must be noted that this regulatory cascade, involving opine-mediated expression of *traR* and TraR–AAI-mediated expression of Ti plasmid transfer genes under conditions of high cell density, has the net effect of enhancing Ti plasmid transfer in the environment of the plant tumor. Given that the Ti plasmid encodes essential virulence proteins for stimulating T-DNA transfer, *A. tumefaciens* might have evolved this complex regulatory system to maximize the number of bacterial cells in the vicinity of the plant wound site that are competent for delivery of opine-encoding T-DNA to plant cells.

D. *vir* genes

The Ti plasmid carries an ~35-kb region that harbors at least six operons involved in T-DNA transfer. Two of these operons have a single open reading frame, whereas the remaining operons code for 2–11 open reading frames. The products of the *vir* region direct events within the bacterium that must precede export of a copy of the T-DNA to plant cells. These events include (i) elaboration of the VirA/VirG sensory transduction system for perception of plant-derived signals and transcriptional activation of the *vir* genes, (ii) T-DNA processing into a nucleoprotein particle for delivery to plant nuclei by the VirC, VirD, and VirE proteins, and (iii) assembly of a transenvelope transporter composed of VirB proteins for exporting the T-DNA transfer intermediate across the bacterial envelope.

1. *vir* gene activation

Infection is initiated when bacteria sense and respond to an array of signals, including specific classes of

plant phenolic compounds, monosaccharides, and an acidic pH that are present at a plant wound site (Fig. 2.1). Signal perception is mediated by the VirA/VirG signal transduction system together with ChvE, a periplasmic sugar-binding protein, and possibly other phenolic-binding proteins. VirA was one of the first described of what is recognized as a very large family of sensor kinases identified in bacteria and recently in eukaryotic cells. The members of this protein family typically are integral membrane proteins with an N-terminal extracytoplasmic domain. Upon sensory perception, the kinase autophosphorylates at a conserved histidine residue and then transfers the phosphate group to a conserved aspartate residue on the second component of this transduction pathway, the response regulator. The phosphorylated response regulator coordinately activates transcription of several operons, whose products mediate a specific response to the inducing environmental signal. For the *A. tumefaciens vir* system, the response regulator is VirG, and phosphorylated VirG activates transcription of the six essential *vir* operons and many other Ti plasmid-encoded operons that are dispensable for virulence.

VirA senses all three of the plant-derived signals discussed previously. The most important signal molecules are phenols that carry an *ortho*-methoxy group. The type of substitution at the *para* position distinguishes strong inducers such as acetosyringone from weaker inducers such as ferulic acid and acetovanillone. A variety of monosaccharides, including glucose, galactose, arabinose, and the acidic sugars D-galacturonic acid and D-glucuronic acid, strongly enhance *vir* gene induction. The inducing phenolic compounds and the monosaccharides are secreted intermediates of biosynthetic pathways involved in cell wall repair. Therefore, the presence of these compounds is a general feature of most plant wounds and likely contributes to the extremely broad host range of *A. tumefaciens*. VirA functions as a homodimer, and recent genetic studies support a model indicating that VirA interacts directly with inducing molecules that diffuse across the outer membrane into the periplasm. Sugar-mediated inducing activity occurs via an interaction between sugars and the periplasmic sugar-binding protein ChvE. In turn, ChvE–sugar interacts with the periplasmic domain of VirA to induce a conformational change that increases the sensitivity of VirA to phenolic inducer molecules. The periplasmic domain of VirA also senses the third environmental signal, acidic pH, required for maximal induction of the *vir* genes; however, the underlying mechanism responsible for stimulation of VirA activity is unknown.

On the basis of recent crystallographic analysis of CheY, a homolog of VirG, phosphorylation of this

family of response regulators is thought to induce a conformational change. Phospho-VirG activates transcription of the *vir* genes by interacting with a *cis*-acting regulatory sequence (TNCAATTGAAAPy) called the *vir* box located upstream of each of the *vir* promoters. Interestingly, both nonphosphorylated and phosphorylated VirG bind to the *vir* box, indicating that a phosphorylation-dependent conformation is necessary for a productive interaction with components of the transcription machinery.

III. CHROMOSOMALLY ENCODED VIRULENCE GENES

Most studies of the *A. tumefaciens* infection process have focused on the roles of Ti plasmid genes in T-DNA transfer and opine response. Several essential and ancillary chromosomal genes also have been shown to contribute to *A. tumefaciens* pathogenicity. Although mutations in these genes are often pleiotropic, they generally function to regulate *vir* gene expression or mediate attachment to plant cells.

A. Regulators of *vir* gene expression

At least three groups of chromosomal genes have been identified that activate or repress *vir* gene expression. As described previously, the periplasmic sugar-binding protein ChvE complexed with any of a wide variety of monosaccharides induces conformational changes in VirA, allowing it to interact with phenolic inducers. Interestingly, *chvE* mutants are not only severely compromised for T-DNA transfer but also show defects in chemotaxis toward sugars, suggesting that ChvE interacts both with VirA and with another membrane protein(s) involved in chemotaxis. ChvE therefore plays a dual role in the physiology of *A. tumefaciens* by promoting chemotaxis toward nutrients and by enhancing the transfer efficiency of opine-encoding T-DNA to plant cells.

A second locus codes for Ros, a transcriptional repressor of certain *vir* operons. As described later, the VirC and VirD operons contribute to the T-DNA processing reaction. Although the promoters for these operons are subject to positive regulation by the VirA/VirG transduction system in response to phenolics and sugars, they are also negatively regulated by the Ros repressor. A mutation in *ros* leads to constitutive expression of *virC* and *virD* in the complete absence of VirG protein. Ros binds to a 9-bp inverted repeat, the *ros* box residing upstream of these promoters. In the absence of plant signals, Ros binding to the *virC* and *virD* promoters prevents the T-DNA processing reaction,

whereas in the presence of plant signals Ros repression is counteracted by the VirA/VirG induction system. Interestingly, Ros was recently shown to be a novel prokaryotic zinc finger protein that functions to repress not only the expression of T-DNA processing genes in the absence of a suitable plant host but also the expression of the T-DNA oncogenes in the bacterium.

A second two-component regulatory system has been identified that, like the VirA/VirG transducer pair, senses environmental signals and mounts a behavioral response by modulating gene expression. ChvG is the sensor kinase and ChvI is the response regulator. Null mutations in genes for these proteins result in cells which cannot induce the *vir* genes or grow at an acidic pH of 5.5. The molecular basis underlying the effect of the ChvG and ChvI proteins on *vir* gene expression is unknown.

B. Attachment to plant cells

Binding of *A. tumefaciens* to plant cells is required for T-DNA transfer. Recent evidence indicates there are at least two binding events that may act sequentially or in tandem. The first is encoded by chromosomal loci and occurs even in the absence of the Ti plasmid genes. This binding event directs bacterial binding to many plant cells independently of whether or not the bacterium is competent for exporting T-DNA or the given plant cell is competent for receipt of T-DNA. The second binding event is mediated by a pilus that is elaborated by the *virB* genes (see Section V.B.1).

Binding via the chromosomally encoded attachment loci is a two-step process in which bacteria first attach loosely to the plant cell surface, often in a polar fashion. A series of genes termed *att* are required for this binding reaction. The second step involves a transition resulting in the tight binding of the bacteria to plant cells. The *cel* genes that mediate this form of binding direct the synthesis of cellulose fibrils that emanate from the bacterial cell surface. Recent studies indicate that binding due to these chromosomal functions occurs at specific sites on the plant cell surface. Binding is saturable, suggestive of a limited number of attachment sites on the plant cell, and binding of virulent strains can also be prevented by attachment of avirulent strains. Although the identity of a plant cell receptor(s) has not been definitively established, a good candidate is a vitronectin-like protein found in detergent extracts of plant cell walls. Attachment-proficient *A. tumefaciens* cells bind radioactive vitronectin, whereas attachment-deficient cells do not bind this molecule. Intriguingly, human vitronectin and antivitronection antibodies both inhibit the binding of *A. tumefaciens* to plant cells.

Efficient attachment of bacteria to plant cells also requires the products of three chromosomal loci: *chwA*, *chwB*, and *exoC* (*pscA*). All three loci are involved in the synthesis of transport of a cyclic β -1,2 glucan molecule. Mutations in these genes are pleiotropic, suggesting that β -1,2 glucan synthesis is important for the overall physiology of *A. tumefaciens*. Periplasmic β -1,2 glucan plays a role in equalizing the osmotic pressure between the inside and outside of the cell. It has been proposed that loss of this form of glucan may indirectly disrupt virulence by reducing the activity or function of cell surface proteins. Interestingly, *chw* mutants accumulate low levels of VirB10, one of the proposed components of the T-complex transport system (see Section V), suggesting that β -1,2 glucan might influence T-DNA export across the bacterial envelope by contributing to transporter assembly.

IV. T-DNA PROCESSING

One of the early events following attachment to plant cells and activation of *vir* gene expression in response to plant signals involves the processing of T-DNA into a form which is competent for transfer across the bacterial cell envelope and translocation through the plant plasma membrane, cytosol, and nuclear membrane. The prevailing view, strongly supported by molecular data, is that T-DNA is transferred as a single-stranded molecule that is associated both covalently and noncovalently with Vir proteins. Two proteins identified to date are components of the transfer intermediate: VirD2, an endonuclease that participates in the T-DNA processing reaction, and VirE2, a single-stranded DNA-binding protein which is proposed to associate noncovalently along the length of the single-stranded transfer intermediate (Fig. 2.1). Intriguingly, recent studies have provided strong evidence that *A. tumefaciens* can export the VirE2 SSB to plant cells independently of T-DNA (see Section IV.B).

A. Formation of the transfer intermediate

More than a decade ago, investigators determined that the T-DNA border repeats are cleaved by a strand-specific endonuclease and that the right T-DNA border sequence is essential for and determines the direction of DNA transfer from *A. tumefaciens* to plant cells. The predominant product of this nicking reaction was shown to be a free single-stranded T-DNA molecule that corresponds to one strand of T-DNA. It was noted that these features of the T-DNA processing reaction are reminiscent of early processing events involved in the conjugative transfer of plasmids

between bacterial cells. In the past 10 years, a large body of evidence has accumulated supporting the notion that DNA processing reactions associated with T-DNA transfer and bacterial conjugation are equivalent. Extensive studies have shown that two systems in particular, the T-DNA transfer system and the conjugation system of the broad host-range plasmid RP4, are highly similar. The substrates for the nicking enzymes of both systems, T-DNA border sequences and the RP4 origin of transfer (*oriT*), exhibit a high degree of sequence similarity. Furthermore, the nicking enzymes VirD2 of pTi and TraI of RP4 possess conserved active-site motifs that are located within the N-terminal halves of these proteins. Purified forms of both proteins cleave at the nick sites within T-DNA borders and the RP4 *oriT*, respectively. In the presence of Mg^{2+} , purified VirD2 will catalyze cleavage of oligonucleotides bearing a T-DNA nick site. However, VirD1 is essential for nicking when the nick site is present on a supercoiled, double-stranded plasmid. Both VirD2 and TraI remain covalently bound to the 5' phosphoryl end of the nicked DNA via conserved tyrosine residues Tyr-29 and Tyr-22. Finally, both proteins catalyze a joining activity reminiscent of type I topoisomerases. VirD1 was reported to possess a topoisomerase I activity, but recent work suggests instead that VirD1 supplies a function analogous to TraJ of RP4, which is thought to interact with *oriT* as a prerequisite for TraI binding to an *oriT* DNA-protein complex.

The current model describing the T-DNA and plasmid conjugation processing reactions is that sequence and strand-specific endonucleases initiate processing by cleaving at T-DNA borders and *oriT* sequences, respectively. This reaction is followed by a strand displacement reaction, which generates a free single-stranded transfer intermediate. Concomitantly, the remaining segment of T-DNA or plasmid serves as a template for replacement synthesis of the displaced strand. It is important to note that the single-stranded transfer intermediates of the T-DNA and RP4 transfer systems remain covalently bound to their cognate endonucleases. Considerable evidence suggests that these protein components play essential roles in delivering the respective transfer intermediates across the bacterial envelope.

B. The role of VirE2 SSB in T-DNA transfer

The *virE2* gene codes for a single-stranded DNA-binding protein that binds cooperatively to single-stranded DNA (ssDNA). Early studies supplied evidence that VirE2 binds with high affinity to any

ssDNA *in vitro* and that it binds T-DNA in *A. tumefaciens*. By analogy to other ssDNA-binding proteins (SSBs) that play important roles in DNA replication, VirE2 was proposed to participate in the T-DNA processing reaction by binding to the liberated T-strand and preventing it from reannealing to its complementary strand on the Ti plasmid. The translocation-competent form of DNA therefore has been depicted as a ssDNA molecule covalently bound at the 5' end by VirD2 and coated along its length with an SSB. The single-stranded form of T-DNA delivered to plants is termed the T-strand, and the VirD2–VirE2–T-strand nucleoprotein particle is termed the T-complex (Fig. 2.1).

Considerable evidence indicates that the T-complex represents the biologically active transfer intermediate. The T-complex, composed of a 20-kb T-strand capped at its 5' end with a 60-kDa endonuclease and approximately 600 VirE2 molecules along its length, is a large nucleoprotein complex of an estimated size of 50×10^6 Da. This size approaches that of some bacteriophages, and it has been questioned whether such a complex could be exported intact across the *A. tumefaciens* envelope without lysing the bacterial cell. Although this is still unknown, several recent discoveries support an alternative model that assembly of the T-complex initiates within the bacterium but is completed within the plant cell.

Approximately 15 years ago, it was discovered that two avirulent *A. tumefaciens* mutants, one with a deletion of T-DNA and a second with a *virE2* mutation, could induce the formation of tumors when inoculated as a mixture on plant wound sites. To explain this observation, it was postulated that *A. tumefaciens* separately exports VirE2 and VirD2 T-strands to the same plant cell. The *virE2* mutant was proposed to export the VirD2 T-strands (T-DNA donor), and the T-DNA deletion mutant could export the VirE2 protein only (VirE2 donor). Once exported, these molecules could then assemble into a nucleoprotein particle, the T-complex, for transmission to the plant nucleus. In strong support of this model, recent genetic analyses have shown that both the proposed T-DNA donor strain and the VirE2 mutant in the mixed infection experiment must possess an intact transport machinery and intact genes mediating bacterial attachment to the plant cell. Furthermore, current genetic data argue against the possible movement of T-DNA or VirE2 between bacterial cells by conjugation as an alternative explanation for complementation by mixed infection. Finally, a *virE* mutant was shown to incite the formation of wild-type tumors on transgenic plants expressing *virE2*. This finding indicates that VirE2 participates in *A. tumefaciens* pathogenesis by supplying essential functions within the plant.

C. Role of cotransported proteins in T-DNA transfer and plasmid conjugation

As discussed previously, processing of T-DNA and conjugative plasmids results in the formation of a ssDNA transfer intermediate covalently bound at its 5' end to the nicking enzyme. Recent studies have shown that the protein component(s) of these conjugal transfer intermediates participates in the delivery of the DNA to the recipient cell. In the case of T-DNA, the transferred proteins facilitate movement of the T-DNA transfer intermediate to plant nuclei by (i) piloting the T-DNA transfer intermediate across the bacterial envelope and protecting it from nucleases and/or (ii) directing T-DNA movement and integration in plant cells. In the case of the IncP plasmid RP4, TraI relaxase is thought to promote plasmid recircularization, and a primase activity associated with the TraC SSB is considered to be important for second-strand synthesis in the recipient cell.

1. Piloting and protection

A piloting function for VirD2 is suggested by the fact that VirD2 is covalently associated at the 5' end of the T-strand and also from the finding that the T-strand is transferred to the plant cell in a 5'–3' unidirectional manner. A dedicated transporter functions to export substrates to plant cells (see Section V). VirD2 might guide T-DNA export by providing the molecular basis for recognition of the transfer intermediate by the transport machinery. By analogy to other protein substrates exported across the bacterial envelope by dedicated transport machines, VirD2 might have a linear peptide sequence or a protein motif in its tertiary structure that marks this molecule as a substrate for the T-DNA transporter.

Studies of T-DNA integrity in transformed plant cells have shown that the 5' end of the transferred molecule generally is intact, suffering little or no loss of nucleotides as a result of exonuclease attack during transit. By contrast, the 3' end of the transferred molecule typically is often extensively deleted. These findings suggest that a second role of the VirD2 endonuclease is to protect the 5' end of the transfer intermediate from nucleases. Recent molecular studies have also shown that T-DNA transferred to plant cells by an *A. tumefaciens virE2* mutant is even more extensively degraded than T-DNA transferred by wild-type cells, suggesting that VirE2 SSB also functions to protect the DNA transfer intermediate from nucleases during transfer.

2. T-DNA movement and integration

DNA sequence analyses revealed the presence of a bipartite type of nuclear localization sequence (NLS)

near the C terminus of VirD2. The nuclear localizing function of this NLS was confirmed by fusing the *virD2* coding sequence to a reporter gene and demonstrating the nuclear localization of the reporter protein activity in tobacco cells transiently expressing the gene fusion. As predicted, *A. tumefaciens* strains expressing mutant forms of VirD2 with defects in the NLS sequence are very inefficient in delivering T-DNA to plant nuclei. Similar lines of investigation showed that VirE2 also possesses two NLS sequences that both contribute to its delivery to the nuclear pore. Therefore, both VirD2 and VirE2 are proposed to promote T-DNA delivery to and across the plant nuclear membrane. In this context, VirD2 has been shown to interact with a plant NLS receptor localized at the nuclear pore. Of further interest, VirD2 has also been shown to interact with several members of a family of proteins termed cyclophilins. The postulated role for cyclophilins in this interaction is to supply a chaperone function at some stage during T-complex trafficking to the nucleus. *Agrobacterium tumefaciens* has been demonstrated to transport DNA to representatives of prokaryotes, yeasts, and plants. Cyclophilins are ubiquitous proteins found in all these cell types and therefore may be of general importance for *A. tumefaciens*-mediated DNA transfer.

T-DNA integrates into the plant nuclear genome by a process termed "illegitimate" recombination. According to this model, T-DNA invades at nicks or gaps in the plant genome possibly generated as a consequence of active DNA replication. The invading ends of the single-stranded T-DNA are proposed to anneal via short regions of homology to the unnicked strand of the plant DNA. Once the ends of T-DNA are ligated to the target ends of plant DNA, the second strand of the T-DNA is replicated and annealed to the opposite strand of the plant DNA. Recent mutational analysis of VirD2 showed that a C-terminal sequence termed Ω appears to play a role in promoting T-DNA integration. A recent study also supports a model that VirE2 also participates in the T-DNA integration step, but the precise functions of VirD2, VirE2, and possible host proteins in this reaction have not been defined.

V. THE T-DNA TRANSPORT SYSTEM

A. The essential components of the T-complex transporter

Exciting progress has been made during the past 6 years on defining the structure and function of the transporter at the *A. tumefaciens* cell surface that is dedicated to exporting the T-DNA transfer intermediate to plant cells.

Early genetic studies suggested that products of the ~9.5-kb *virB* operon are the most likely candidates for assembling into a cell surface structure for translocation of T-DNA across the *A. tumefaciens* envelope. Sequence analyses of the *virB* operon have supported this prediction by showing that the deduced products have hydropathy patterns characteristic of membrane-associated proteins. Recently, a systematic approach was taken to delete each of the 11 *virB* genes from the *virB* operon without altering expression of the downstream genes. Analyses of this set of nonpolar null mutants showed that *virB2*–*virB11* are essential for T-DNA transfer, whereas *virB1* is dispensable. As described in more detail later, the VirB proteins, along with the VirD4 protein, are thought to assemble at the cell envelope as a channel dedicated to the export of T-complexes.

B. The T-complex transporter

1. Type IV transporters: DNA conjugation systems adapted for export of virulence factors

DNA sequence studies within the past 4 years have identified extensive similarities between products of the *virB* genes and components of two types of transporters dedicated to movement of macromolecules from or between cells (Fig. 2.4). The first type, encoded by *tra* operons of conjugative plasmids, functions to deliver conjugative plasmids to bacterial recipient cells. The IncN plasmid, pKM101, and the IncW plasmid, R388, code for Tra protein homologs of each of the VirB proteins. Furthermore, the genes coding for related proteins are often colinear in these respective *virB* and *tra* operons, supporting the view that these DNA transfer systems share a common ancestral origin. Other broad host-range plasmids such as RP4 (IncP α) and the narrow host-range plasmid F (IncF) code for proteins homologous to a subset of the VirB proteins.

DNA sequence studies also identified a related group of transporters in several bacterial pathogens of humans that function not to export DNA but rather to secrete protein toxins (Fig. 2.4). *Bordetella pertussis*, the causative agent of whooping cough, uses the Ptl transporter to export the six-subunit pertussis toxin across the bacterial envelope. All nine Ptl proteins have been shown to be related to VirB proteins, and the *ptl* genes and the corresponding *virB* genes are colinear in their respective operons. Type I strains of *Helicobacter pylori*, the causative agent of peptic ulcer disease and a risk factor for development of gastric adenocarcinoma, contain a 40-kb *cag* pathogenicity island (PAI) that codes for several virulence factors, of which several are related to Vir proteins. These Cag proteins are thought to assemble into a transporter for

FIGURE 2.4 Alignment of genes encoding related components of the type IV transport systems. Of the 11 VirB proteins, those encoded by *virB2–virB11*, as well as *virD4*, are essential for T-complex transport to plant cells. The broad host-range (BHR) plasmid pKM101 encodes a conjugation apparatus composed of the products of the *tra* genes shown. Other BHR plasmids and the narrow host-range (NHR) F plasmid code for Tra proteins related to most or all the VirB genes. A second subfamily of type IV transporters found in bacterial pathogens of humans export toxins or other protein effectors to human cells.

exporting an unidentified protein toxin(s) that induces synthesis of the proinflammatory cytokine IL-8 in gastric epithelial cells. Finally, *Legionella pneumophila*, the causative agent of Legionnaire's disease and Pontiac fever, possesses the *icm/dot* genes, of which *dotG* and *dotB* code for proteins related to VirB10 and VirB11 and others code for homologs of transfer proteins encoded by other bacterial conjugation systems. The Icm/Dot proteins are proposed to assemble into a transporter that exports a virulence factor(s) that promotes intracellular survival of *L. pneumophila* and macrophage killing.

The transporters described previously are grouped on the basis of evolutionary relatedness as a distinct transport family. Designated as the type IV secretion family, this classification distinguishes these transporters from other conserved bacterial protein targeting mechanisms that have been identified in bacteria. Although this is a functionally diverse family, the unifying theme of the type IV transporters is that each system has evolved by adapting an ancestral DNA conjugation apparatus or a part of this apparatus for the novel purpose of exporting DNA or proteins that function as virulence factors.

2. Functional similarities among type IV transporters

Functional studies have supplied compelling evidence that the type IV transporters are mechanistically related. The non-self-transmissible plasmid RSF1010

of the IncQ incompatibility group possesses an *oriT* sequence and mobilization (*mob*) functions for generating a ssDNA transfer intermediate. This transfer intermediate can be delivered to recipient bacteria by the type IV transporters of the IncN, IncW, IncP, and F plasmids. In addition, approximately 10 years ago it was shown using an *A. tumefaciens* strain harboring a disarmed Ti plasmid (with *vir* genes but lacking the T-DNA or its borders) and an RSF1010 derivative that the T-complex transporter could deliver the IncQ transfer intermediate to plant cells. This discovery was followed soon afterwards by the demonstration that the T-complex transporter also functions to conjugally deliver the IncQ plasmid to *A. tumefaciens* recipient cells. Interestingly, *A. tumefaciens* strains carrying both an IncQ plasmid and an intact T-DNA efficiently deliver the IncQ plasmid to plant cells but do not transfer the T-DNA. Preferential transfer of the IncQ plasmid over the T-DNA transfer intermediate could result from the transporter having a higher affinity for the IncQ plasmid or the IncQ plasmid being more abundant than the T-DNA. Of further interest, the coordinate overexpression of *virB9*, *virB10*, and *virB11* relieved the IncQ suppression and restored efficient T-DNA transfer to plant cells. These findings suggest that the T-complex and the IncQ transfer intermediate compete for the same transport apparatus. Furthermore, the data suggest that VirB9–VirB11 stoichiometries determine the number of transporters a given cell can assemble or influence the selection of substrates destined for export.

Although the toxin substrates have not been identified for the *H. pylori* Cag and *L. pneumophila* Dot/Icm transporters, it is intriguing to note that the Dot/Icm system also has been shown to deliver the non-self-transmissible IncQ plasmid RSF1010 to bacterial recipient cells by a process requiring cell-to-cell contact. Also, as observed for T-complex export, the presence of an IncQ plasmid suppresses export of the natural substrate of the Dot/Icm transporter of *L. pneumophila*, resulting in inhibition of intracellular multiplication and human macrophage killing. These parallel findings show that the type IV DNA and protein export systems are highly mechanistically related.

C. Architecture of the T-complex transporter

The T-complex transporter, like other DNA conjugation machines, is proposed to be configured as a transenvelope channel through which the T-DNA transfer intermediate passes and as an extracellular pilus termed the T-pilus for making contact with recipient cells. Most of the VirB proteins fractionate with both membranes, consistent with the view that these proteins assemble as a membrane-spanning protein channel. All the VirB proteins except VirB11 possess periplasmic domains, as shown by protease susceptibility and reporter protein fusion experiments. Although detailed structural information is not available for the T-complex transporter, important progress has been made in the characterization of the VirB proteins, especially in the following areas: (i) characterization of the *virB*-encoded pilus termed the T-pilus, (ii) structure–function studies of the VirB4 and VirB11 ATPases, and (iii) identification of a nucleation activity of a disulfide cross-linked VirB7/VirB9 heterodimer during transporter assembly (Table 2.1).

1. The T-pilus

The type IV systems involved in conjugation elaborate pili for establishing contact between plasmid-bearing donor cells and recipient cells. Recent studies have demonstrated that VirB proteins direct the assembly of a pilus which is essential for T-DNA transfer. Electron microscopy studies have demonstrated the presence of long filaments (~10 nm in diameter) on the surfaces of *A. tumefaciens* cells induced for expression of the *virB* genes. These filaments are absent from the surfaces of mutant strains defective in the expression of one or more of the *virB* genes. Furthermore, an interesting observation was made that cells grown at room temperature rarely possess pili, whereas cells grown at ~19°C possess these structures in abundance. This finding correlates well with previous findings that low temperature

TABLE 2.1 Properties of the VirB proteins

VirB	Localization	Proposed function
B1	Periplasm	Transglycosylase
B1*	Cell exterior	Cell contact/pilin subunit?
B2	Exported/cell exterior	Cell contact/pilin subunit
B3	Exported	Unknown
B4	Transmembrane	ATPase/transport activation

B6	Transmembrane	Candidate pore former
B7	Outer membrane	Lipoprotein/transporter assembly
B8	Periplasmic face of inner membrane	Unknown
B9	Outer membrane	Lipoprotein/transporter assembly
B10	Transmembrane	Coupler of inner and outer membrane subcomplexes?
B11	Cytoplasm/inner membrane	ATPase/transport activation
D4	Transmembrane	ATPase/coupler of DNA processing and transport systems

stimulates the *virB*-dependent transfer of IncQ plasmids to bacterial recipients and T-DNA transfer to plants.

Recently, compelling evidence demonstrated that VirB2 is the major pilin subunit. Early studies showed that VirB2 bears both sequence and structural similarity to the TraA pilin subunit of the F plasmid of *E. coli*. Recent work demonstrated that VirB2, like TraA, is processed from an ~12-kDa propilin to a 7.2-kDa mature protein that accumulates in the inner membrane. During F plasmid conjugation, TraA is mobilized to the surface of the donor cell where it polymerizes to form the pilus. Similarly, the appearance of pili on the surface of *A. tumefaciens* cells induced for expression of the *vir* genes is correlated with the presence of VirB2 on the cell exterior. Finally, VirB2 is a major component of pili that have been sheared from the cell surface and purified.

Many adhesive and conjugative pili possess one or more minor pilin subunits in addition to the major pilin structural protein. Interestingly, VirB1, a periplasmic protein with transglycosylase activity, is processed such that the C-terminal two-thirds of the protein, termed VirB1*, is secreted to the outer surface of the cell. This localization is consistent with a proposed function for VirB1* as a minor pilin subunit. VirB5 might also assemble as a pilin subunit based on its homology to a possible pilin subunit encoded by the IncN plasmid pKM101 transfer system.

2. Studies of the VirB ATPases

Two VirB proteins, VirB4 and VirB11, possess conserved mononucleotide-binding motifs. Mutational

analyses established the importance of these motifs for the function of both proteins. In addition, purified forms of both proteins exhibit weak ATPase activities, suggesting that VirB4 and VirB11 couple the energy of ATP hydrolysis to transport. Both of these putative ATPases appear to contribute functions of general importance for macromolecular transport since homologs have been identified among many DNA and protein transport systems. Of further possible significance, VirB11 and two homologs, TrbB of IncP RP4 and EpsE, of *Vibrio cholerae* have been reported to autophosphorylate. VirB4 and VirB11 might activate substrate transport by using the energy of ATP hydrolysis or a kinase activity to facilitate assembly of the transport apparatus at the cell envelope. Alternatively, by analogy to the SecA ATPase of *E. coli* which uses the energy of ATP hydrolysis to drive translocation of exported proteins, one or both of the VirB ATPases may contribute directly to export of the DNA transfer intermediate. Recent studies have shown that both VirB4 and VirB11 assemble as homodimers. Dimerization is postulated to be critical both for protein stability and for catalytic activity. Accumulation of these ATPases to wild-type levels depends on the presence of other VirB proteins, suggesting that complex formation with other components of the T-complex transporter contributes to protein stability. Specific contacts between these ATPases and other transporter components have not been identified.

3. The VirB7 lipoprotein and formation of stabilizing intermolecular disulfide bridges

Detailed studies have shown that VirB7 is critical for assembly of a functional T-complex transport system. VirB7 possesses a characteristic signal sequence that ends with a consensus peptidase II cleavage site characteristic of bacterial lipoproteins. Biochemical studies have confirmed that VirB7 is processed as a lipoprotein. Furthermore, maturation of VirB7 as a lipoprotein is critical for its proposed role in T-complex transporter biogenesis. Recent studies have shown that the VirB7 lipoprotein interacts directly with the outer membrane protein VirB9. The first hint of a possible interaction between these proteins was provided by the demonstration that VirB9 accumulation is strongly dependent on co-synthesis of VirB7, suggesting that VirB7 stabilizes VirB9. Interestingly, this stabilizing effect has been shown to be mediated by formation of a disulfide bridge between these two proteins. VirB7 assembles not only as VirB7/VirB9 heterodimers but also as covalently cross-linked homodimers, and there is evidence that VirB9 assembles into higher order multimeric complexes. These dimers and

higher order multimers might correspond to stable subcomplexes of the larger transport system. In the case of the VirB7/VirB9 heterodimer, considerable evidence indicates that this heterodimer plays a critical role early during transporter biogenesis by recruiting and stabilizing newly synthesized VirB proteins. The heterodimer has been shown to interact with VirB1*. The heterodimer also interacts with VirB10, a cytoplasmic membrane protein with a large C-terminal periplasmic domain. VirB10 has been postulated to join the VirB7/VirB9 heterodimer at the outer membrane with a VirB protein subcomplex located at the inner membrane.

4. VirB protein stimulation of IncQ plasmid uptake by bacterial recipient cells

The T-complex transport system seems designed to function unidirectionally to export substrates to recipient cells. However, a recent discovery indicates that VirB proteins can also assemble as a transenvelope structure that stimulates DNA uptake during conjugation. The fundamental observation is that *A. tumefaciens* cells harboring an IncQ plasmid conjugally transfer the IncQ plasmid to recipient cells expressing the *virB* genes at a frequency of ~1000 times that observed for transfer to recipient cells lacking the *virB* genes. Furthermore, only a subset of *virB* genes, including *virB3*, *virB4*, and *virB7-virB10*, was required for enhanced DNA uptake by recipient cells. These findings suggest that a subset of the VirB proteins might assemble as a core translocation channel at the bacterial envelope that accommodates the bidirectional transfer of DNA substrates. Such a channel might correspond to an early assembly intermediate that, upon complex formation with additional VirB proteins, is converted to a dedicated T-complex export system.

VI. AGROBACTERIUM HOST RANGE

One of the most appealing features of the *A. tumefaciens* DNA transfer system for genetic engineering is its extremely broad host range. Pathogenic strains of *Agrobacterium* infect a wide range of gymnosperms and dicotyledonous plant species of agricultural importance. Crown gall disease can cause devastating reductions in yields of woody crops such as apples, peaches, and pears and vine crops such as grapes. Various host range determinants present in different *A. tumefaciens* strains determine whether a given bacterial strain is virulent for a given plant species.

A. Transformation of monocots

In the past 5 years, dramatic progress has been made toward the development of protocols for stably transforming agriculturally important monocotyledonous plant species. The first indication of gene transfer involved the introduction of a plant viral genome into a plant host via *A. tumefaciens*-mediated transfer of T-DNA carrying the viral genome. Once inside the plant host, the viral DNA excises from the T-DNA and infects the host, inciting disease symptoms that are characteristic of the virus. This process, termed agroinfection, supplied compelling evidence that *A. tumefaciens* transfers T-DNA to monocot plants such as maize. A notable feature of agroinfection is that the introduced viral DNA incites disease without incorporating into the plant genome. Early efforts to obtain stable transformation of monocot species were unsuccessful. The demonstration of agroinfection and the inability to demonstrate T-DNA integration together led to the suggestion that the T-DNA integration step was somehow blocked in monocots. However, protocols have been developed for the efficient and reproducible stable transformation of rice, corn, wheat, and other monocot species. Key to the success of these protocols was the use of actively dividing cells such as immature embryos. In addition, preinduction of *A. tumefaciens* with phenolic inducers appears to enhance T-DNA transfer efficiencies. Additional factors, such as plant genotype, the type and age of plant tissue, the kinds of vectors and bacterial strains, and the types of selectable genes delivered to plant cells, influence the transformation efficiencies. For rice and corn, most of these parameters have been optimized, so that the delivery of foreign DNA to these crop plants is a routine technique.

B. Gene transfer to yeast and fungi

Intriguing recent work has extended the host range of *A. tumefaciens* beyond the plant kingdom to include budding and fission yeast and many species of filamentous fungi. The successful transfer of DNA to yeast depends on the presence of stabilizing sequences, such as a yeast origin of replication sequence or a telomere, or regions of homology between the transferred DNA and the yeast genome for integration by homologous recombination. When the T-DNA lacks any extensive regions of homology with the *Saccharomyces cerevisiae* genome, it integrates at random positions by illegitimate recombination reminiscent of T-DNA integration in plants (see Section IV.C.2). The transformation of filamentous fungi with *A. tumefaciens* is an exciting advancement. *Agrobacterium tumefaciens* was

shown to efficiently deliver DNA to fungal protoplasts and fungal conidia and hyphal tissue. This discovery extends well beyond academic interest because the simplicity and high efficiency make this gene delivery system an extremely useful tool for the genetic manipulation and characterization of fungi. This DNA transfer system is especially valuable for species such as the mushroom *Agaricus bisporus* which are recalcitrant to transformation by other methods. It is also of interest to consider that both *A. tumefaciens* and many fungal species exist in the same soil environment, raising the possibility that *A. tumefaciens*-mediated gene transfer to fungi may not be restricted solely to the laboratory bench.

VII. GENETIC ENGINEERING OF PLANTS AND OTHER ORGANISMS

The extent to which any biological system is understood is reflected by our ability to manipulate that system to achieve novel ends. For *A. tumefaciens* transformation, the holy grail has been monocot transformation. As described previously, exciting progress has been made toward attaining this objective for several agriculturally important monocot species. Currently, plant genetic engineers are developing the *A. tumefaciens* gene delivery to achieve equally challenging goals such as (i) designing T-DNA tagging methods for isolating and characterizing novel plant genes, (ii) designing strategies to deliver foreign DNA to specific sites in the plant genome, and (iii) characterizing and genetically engineering other organisms such as agriculturally or medically important fungi.

A. Overcoming barriers to transformation

It is remarkable that all progress in *A. tumefaciens*-mediated monocot transformation has been achieved in the intervening period between the publication of the first and second editions of this encyclopedia. In fact, currently *A. tumefaciens* is the biological DNA delivery system of choice for transformation of most dicot and monocot plant species. The reasons are twofold. First, *A. tumefaciens* is readily manipulated such that plasmids carrying foreign genes of interest are easily introduced into appropriate bacterial strains for delivery to plants. Typically, strains used for gene delivery are "disarmed," that is, deleted of oncogenic T-DNA but still harboring intact Ti plasmid and chromosomal *vir* genes. Foreign genes destined for delivery to plants generally are cloned onto a plasmid that carries a single T-DNA border sequence or

two T-DNA border sequences that flank various restriction sites for cloning as well as an antibiotic resistance gene to select for transformed plant cells. If the plasmid carries a single border sequence, the entire plasmid is delivered to plants, and recent work indicates that *A. tumefaciens* can deliver as much as 180-kb of DNA to plants. If the plasmid carries two border sequences, only the DNA bounded by T-DNA borders is delivered to plants. Second, the frequency of stable transformation is often very high, far exceeding frequencies achieved by other gene delivery methods. For example, co-cultivation of *A. tumefaciens* with regenerating protoplasts of certain plant species can result in transformation of up to one-half of the protoplasts.

However, with protoplast transformation there is often a significant reduction in the number of transgenic, fertile plants recovered during selective regeneration of transformed protoplasts. For certain species, protoplasts can be transformed but are recalcitrant to regeneration into intact plants. Consequently, other transformation methods have relied on transformation of plant tissues such as excised leaves or root sections. In the case of monocot species such as maize, immature embryos are the preferred starting material for *A. tumefaciens*-mediated DNA transfer. For rice, success has been achieved with callus tissue induced from immature embryos.

In addition to the need to identify transformable and regenerable plant tissues, many varieties of a given species often need to be screened to identify the susceptible varieties. A large variation in transformation efficiencies is often observed depending on which cell line is being tested. This underscores the notion that interkingdom DNA transfer is a complex process dependent on a genetic interplay between *A. tumefaciens* and host cells. Fortunately, many of the agronomically important species are readily transformable, but additional efforts are needed to overcome the current obstacles impeding efficient transformation of other species of interest.

B. Other applications

Agrobacterium tumefaciens is increasingly used to characterize and isolate novel plant genes by an approach termed T-DNA tagging. Several variations to this methodology exist depending on the desired goals. For example, because insertions are generally randomly distributed throughout the plant genome, T-DNA is widely used as a mutagen for isolating plant genes with novel phenotypes. If the mutagenic T-DNA carries a bacterial origin of replication, the mutated gene of interest can easily be recovered in

bacteria by suitable molecular techniques. Furthermore, if the T-DNA is engineered to carry a selectable or scorable gene near one of its ends, insertion downstream of a plant promoter will permit characterization of promoter activity. Conversely, if the T-DNA is engineered to carry an outward reading promoter, insertion can result in a modulation of gene expression with potentially interesting phenotypic consequences. Finally, the discovery that *A. tumefaciens* can transform fungal species of interest means that all approaches developed for plants can be applied to the characterization of fungi.

Although random T-DNA insertion is a boon to investigators interested in characterizing plant or fungal genes, it is an undesired event for plant genetic engineering. In addition to the potential result that T-DNA will insert into an essential gene, insertion often is accompanied by rearrangements of flanking sequences, thus further increasing the chances that the insertion will have undesired consequences. Ideally, T-DNA could be delivered to a restricted number of sites in the plant genome. Recent progress toward this goal has involved the use of the bacteriophage P1 Cre/lox system for site-specific integration in the plant genome. The Cre site-specific recombinase catalyzes strand exchange between two lox sites which, for P1, results in circularization of the P1 genome upon infection of bacterial cells. For directed T-DNA insertion, both the plant and the T-DNA are engineered to carry lox sequences and the plant is also engineered to express the Cre protein. Upon entry of T-DNA into the plant cell, Cre was shown to catalyze the site-specific integration of T-DNA at the plant lox site. The frequency of directed insertion events is low compared to random insertion events, but additional manipulation of this system should enhance its general applicability.

VIII. CONCLUSIONS

The early discovery that oncogenes can be excised from T-DNA and replaced with genes of interest paved the way for the fast growing industry of plant genetic engineering. Currently, much information has been assembled on the *A. tumefaciens* infection process. This information has been used to successfully manipulate the T-DNA transfer system both to enhance its efficiency and to broaden the range of transformable plants and other organisms. Furthermore, it must be noted that this information has also often established a conceptual framework for initiating or extending the characterization of other pathogenic and symbiotic relationships. The discovery that secreted chemical signals initiate a complex

dialogue between *A. tumefaciens* and plant cells as well as other *A. tumefaciens* cells has stimulated a global effort to identify extracellular signals and characterize the cognate signal transduction systems in many bacterial systems. The discovery of T-DNA transport provided a mechanistic explanation for how horizontal gene transfer impacts the evolution of genomes of higher organisms. This discovery also established a precedent for interkingdom transport of virulence factors by bacterial pathogens. Indeed, in only the past 6 years, studies have revealed that numerous pathogens employ interkingdom transport to deliver a wide array of effector proteins to plant and animal hosts. These so-called type III transport systems, like the *A. tumefaciens* T-complex transporter and related type IV transporters, deliver substrates via a process dependent on cell-to-cell contact and, in some cases, elaboration of an extracellular filament or pilus. It is clear that, in the future, studies of all the various aspects of the *A. tumefaciens* infection process will continue to spawn new applications for this novel DNA transfer system and yield new insights about the evolution and function of pathogenic mechanisms that are broadly distributed in nature.

Antibiotic resistance in bacteria

Julian Davies

University of British Columbia

Vera Webb

Lookfar Solutions Inc., British Columbia

We must swim with the microbes and study their survival and adaptation to new habitats.

Richard M. Krause (1994).

GLOSSARY

Broad-spectrum antibiotic A drug that affects a wide range of bacteria.

Cell wall, bacterial A rigid outer layer of bacterial cells containing peptidoglycan.

Integron A mobile genetic element that serves as the site of integration for DNA. It encodes a site-specific recombinase called integrase.

Multidrug Efflux Pumps Mechanisms for exporting a number of compounds across the cell membrane.

Peptidoglycan or Murein A long chain of disaccharides consisting of N-acetylglucosamine and muramic acid with short peptides that are often cross linked to give a mesh-like two-dimensional structure. Its synthetic machinery is the target for β -lactam antibiotics.

Protein synthesis machinery A large complex of proteins and RNAs, including ribosome, transfer RNAs (tRNA), messenger RNA (mRNA), proteins, and small molecules.

Resistance determinants (or R determinants) Genes that confer antibiotic resistance.

Target for antibiotics Ideally, a constituent present in the target cell (e.g., bacterial pathogen, cancer cell) and not present in the host.

I. INTRODUCTION

The development of antibiotic resistance can be viewed as a global problem in microbial genetic ecology. It is a very complex problem to contemplate, let alone solve, due to the geographic scale, the variety of environmental factors, and the enormous number and diversity of microbial participants. In addition, the situation can only be viewed retrospectively, and what has been done was uncontrolled and largely unrecorded. Simply put, since the introduction of antibiotics for the treatment of infectious diseases in the late 1940s, human and animal microbial ecology has been drastically disturbed. The response of microbes to the threat of extinction has been to find genetic and biochemical evolutionary routes that led to the development of resistance to every antimicrobial agent used. The result is a large pool of resistance determinants in the environment. The origins, evolution, and dissemination of these resistance genes is the subject of this review.

II. MECHANISMS OF RESISTANCE: BIOCHEMISTRY AND GENETICS

The use of antibiotics should have created a catastrophic situation for microbial populations; however, their genetic flexibility allowed bacteria to survive (and even thrive) in hostile environments. The alternatives for survival for threatened microbial populations were either mutation of target sites or acquisition of novel

biochemical functions (also known as resistance determinants or R determinants).¹ Table 3.1 lists antibiotic resistance mechanisms that are transferable among bacteria. Mutation and the acquisition of R determinants are not mutually exclusive resistance strategies. Under the selective pressure of the antibiotic, mutation can lead to “protein engineering” of the acquired resistance determinant which may expand its substrate range to include semisynthetic molecules designed to be refractory to the wild-type enzyme (see Section II.A.2.a).

Theoretically, the ideal target for a chemotherapeutic agent is a constituent which is present in the target cell (e.g. bacterial pathogen, cancer cell) and not present in the host cell. The first antibiotics to be employed generally, the penicillins, targeted the synthesis of peptidoglycan, a component unique to the bacterial cell wall. Antibiotics have been found that inhibit the synthesis or interfere with the function of essentially all cellular macromolecules. Table 3.2 lists some of the common antimicrobial drugs used clinically and their targets within the bacterial cell. Our discussion of the mechanisms of resistance will be organized according to the targets of antibiotic activity.

A. Targets and specific mechanisms

1. Protein synthesis

Protein synthesis involves a number of components: the ribosome, transfer RNA (tRNA), messenger RNA (mRNA), numerous ancillary proteins, and other small molecules. When protein synthesis is inhibited by the action of an antibiotic, the ribosome is usually the target. The bacterial ribosome is composed of two riboprotein subunits. The small, 30 S subunit consists of approximately 21 ribosomal proteins (rprotein) and the 16 S ribosomal RNA (rRNA) molecule (about 1500 nucleotides), whereas the large, 50 S subunit contains approximately 34 rproteins and the 23 S and 5 S rRNA molecules (about 3000 and 120 nucleotides, respectively). The complexity of the ribosome structure and the redundancy of many of the genes encoding ribosomal components in most bacterial genera makes resistance due to point mutation an unlikely event. Generally, resistance to antibiotics that inhibit protein synthesis is mediated by R determinants.

a. Aminoglycosides

Aminoglycosides, which are broad-spectrum antibiotics, are composed of three or more aminocyclitol units.

¹A note concerning terminology: “determinant” refers to the genetic element which encodes a “mechanism” or biochemical activity which confers resistance.

TABLE 3.1 Transferable antibiotic resistance mechanisms in bacteria

Mechanism	Antibiotic
Reduced uptake into cell	Chloramphenicol
Active efflux from cell	Tetracyclines
Modification of target to eliminate or reduce binding of antibiotic	β -Lactams Erythromycin Lincomycin Mupirocin
Inactivation of antibiotic by enzymatic modification	
Hydrolysis	β -Lactams Erythromycin
Derivatization	Aminoglycosides Chloramphenicol Lincomycin
Sequestration of antibiotic by protein binding	β -Lactams Fusidic acid
Metabolic bypass of inhibited reaction	Trimethoprim Sulfonamides
Binding of specific immunity protein	Bleomycin
Overproduction of antibiotic target (titration)	Trimethoprim Sulfonamides

TABLE 3.2 Antimicrobial drugs: mechanisms of action

Target	Drug
Protein synthesis	
30 S subunit	Tetracyclines Aminoglycosides: streptomycin, amikacin, apramycin, gentamicin, kanamycin, tobramycin, netilmicin, isepamicin
50 S subunit	Chloramphenicol Fusidic acid Macrolides: erythromycin, streptogramin B Lincosamides
tRNA synthetase	Mupirocin
Cell wall synthesis	
Penicillin binding proteins	β -Lactams Penicillins: ampicillin, methicillin, oxacillin Cephalosporins: cefoxitin, cefotaxime Carbapenems: imipenem β -Lactamase inhibitors: clavulanic acid, sulbactam
D-Ala-D-Ala binding	Cyclic glycopeptides: vancomycin, teicoplanin, avoparcin
Muramic acid biosynthesis	Fosfomycin
Nucleic acid synthesis	
DNA	Quinolones and fluoroquinolones: ciprofloxacin, sparfloxacin
RNA	Rifampicin
Folic acid metabolism	Trimethoprim Sulfonamides

They bind to the 30 S subunit and prevent the transition from the initiated complex to the elongation complex; they also interfere with the decoding process. As noted above, target site mutations of ribosomal components resulting in antibiotic resistance are rare; however, they do occur. For example, in the slow-growing *Mycobacterium tuberculosis*, mutants resistant to streptomycin appear more frequently than they do in *Escherichia coli*. Mutations leading to resistance result from an altered S12 rprotein or 16 S rRNA such that the ribosome has reduced affinity for the antibiotic. Most fast-growing bacteria have multiple copies of the rRNA genes, and because resistance is genetically recessive to antibiotic sensitivity, only rare mutations in the gene for protein S12 are isolated under normal situations. However, because the slow-growing mycobacteria possess only single copies of the rRNA genes, streptomycin resistance can arise by mutational alteration of either 16 S rRNA or ribosomal protein S12. Both types of mutations have been identified in *M. tuberculosis* (Finken *et al.*, 1993).

The introduction and therapeutic use of a series of naturally occurring and semisynthetic aminoglycosides over a 20-year period (1968–1988) led to the appearance of multiresistant strains resulting from selection and dissemination of a variety of aminoglycoside resistance determinants. For example, in 1994 the Aminoglycoside Resistance Study Group examined the occurrence of aminoglycoside-resistance mechanisms in almost 2000 aminoglycoside-resistant *Pseudomonas* isolates from seven different geographic regions. In their study 37% of the isolates overall had at least two different mechanisms of resistance (Aminoglycoside Resistance Study Group, 1994).

A dozen different types of modifications are known to be responsible for resistance to the aminoglycosides. When one considers that each of these enzymes has a number of isozymic forms, there are at least 30 different genes implicated in bacterial resistance to this class of antibiotics. Different proteins in the same functional class may show as little as 44% amino acid similarity. The phylogenetic relationships between different aminoglycoside-modifying enzymes were the subject of an excellent review by Shaw and co-workers, who have collated the nucleotide and protein sequences of the known aminoglycoside acetyltransferases, phosphotransferases, and adenylyltransferases responsible for resistance in both pathogenic bacteria and antibiotic-producing strains (Shaw *et al.*, 1993).

Rarely do a few point mutations in the aminoglycoside resistance gene arise sufficient to generate a modified enzyme with an altered substrate range that would lead to a significant change in the antibiotic resistance spectrum (Rather *et al.*, 1992; Kocabiyik and Perlin, 1992); in other words, these genes do not

appear to undergo facile mutational changes that generate enzymes with altered substrate activity. *In vitro* mutagenesis studies have failed to generate extended-spectrum resistance to this class of antibiotics, and, so far, such changes have not been identified in clinical isolates, in contrast to the situation with the β -lactamases (see Section II.B.2). The bacterial response to the introduction of a new aminoglycoside antibiotic is to acquire a different resistance gene. For example, when the use of kanamycin was superseded by a new but structurally related aminoglycoside (gentamicin), a previously unknown class of antibiotic-inactivating enzymes was detected in the gentamicin-resistant strains that appeared in hospitals.

Many gram-positive pathogens possess an unusual bifunctional aminoglycoside-modifying enzyme, the only reported instance of fused resistance genes. The enzyme encodes acetyl- and phosphotransferase activities based on protein domains acquired by the fusion of two independent resistance genes (Ferretti *et al.*, 1986; Rouch *et al.*, 1987). The hybrid gene is widely distributed among hospital isolates of staphylococci and enterococci and can be assumed to have evolved as a fortuitous gene fusion during the process of insertion of the two resistance genes into the "cloning" site of a transposon. The therapeutic use of aminoglycoside antibiotics has decreased in recent years, largely because of the introduction of the less toxic broad-spectrum β -lactams. As a result, there has been a relatively limited effort to seek specific inhibitors of the aminoglycoside-modifying enzymes, which might have offered therapeutic potential to extend the effective range of this class of antibiotics. Although some active inhibitors have been identified, none of them has been deemed fit for introduction into clinical practice. The situation may change as a result of structural studies by Puglisi and co-workers (Fourmy *et al.*, 1996). Employing three-dimensional (3-D) nuclear magnetic resonance techniques, they were able to model the aminoglycoside paromomycin into its binding site (the decoding site) in a 16 S RNA fragment. The logical extension of this important information, which identifies the key binding functions on the antibiotic, would be to design aminoglycoside molecules that: (a) could bind to a resistant ribosome modified by base substitution or methylation; or (b) might be refractory to modification by one or more of the aminoglycoside-modifying enzymes yet retain high affinity to the rRNA receptor site. This aminoglycoside/rRNA binding is the first to be characterized at this level of resolution and may permit the design and production of not only aminoglycoside analogs refractory to modification but also those which have reduced affinity for mammalian ribosomes; the latter is an important component of aminoglycoside toxicity.

b. Tetracycline

Tetracyclines are perhaps the prime example of the development of antibiotic resistance; introduced in the late 1940s, they were the first group of broad-spectrum antibiotics (penicillin use was limited mostly to infections caused by gram-positive bacteria). Tetracyclines act by blocking the binding of aminoacyl-tRNAs to the A-site of the ribosome. They are active against most types of bacteria including gram-positives, gram-negatives, mycoplasmas, chlamydiae, and rickettsiae. This broad spectrum of activity and their relative safety, and low cost, have made tetracyclines the second most widely used group of antimicrobial agents after the β -lactams. It is probable that larger quantities of the tetracyclines have been produced and used than any other antibiotic. From a point of view of antibiotic resistance, almost everything that could have happened to the tetracyclines has done so! In 1953, just 6 years after their discovery, the first tetracycline-resistant *Shigella dysenteriae* were isolated in Japan. They were the earliest of the antibiotic substances to be used as feed additives in agriculture; enormous amounts have been dispensed in the last 40 years. In addition, because of their spectrum of activity, the tetracyclines became widely dispensed in both hospitals and the community. In many countries tetracycline has been virtually an over-the-counter drug for many years. As a result resistance to the tetracyclines is widely disseminated in many forms (see Tables 3.3 and 3.4). This class of antibiotics has become a paradigm for antibiotic resistance studies, and a number of useful reviews of tetracycline resistance have appeared (Hillen and Berens, 1994; Roberts, 1994).

Because tetracyclines are extensively used, one might expect that resistance is also widespread (Table 3.3). At least 16 different tetracycline-resistance (Tet) determinants from "target organisms" and three different oxytetracycline-resistance (Otr) determinants from the producing organisms, *Streptomyces* species, have been described and characterized (Table 3.4). The majority of these determinants (13), are plasmid encoded. For example, the genes encoding TetA–E are found on plasmids in gram-negative bacteria, while those for TetK and TetL are found only in gram-positive microbes. The TetM determinant is generally found on the chromosome of both gram-negative and gram-positive bacteria, while TetO in gram-negative and TetK genes in gram-positive organisms have been detected in either location.

Three different mechanisms for tetracycline resistance have been described: (a) energy-dependent efflux of tetracycline from the cell; (b) ribosome protection (summarized in Table 3.4); and (c) enzymatic

TABLE 3.3 Distribution of tetracycline-resistance determinants among various bacterial genera

TetB(P)	Plasmid
OtrA	Chromosome

inactivation of tetracycline; only the first two mechanisms have been shown to have clinical significance. The majority of the Tet determinants code for a membrane-bound efflux protein of about 46 kilodaltons (kDa). Nucleotide sequence analysis of the genes encoding these proteins indicate that they are members of the so-called major facilitator (MF) family of efflux proteins (Sheridan and Chopra, 1991; Marger and Saier, 1993) (see Section II.B.2 and Table 3.5). The

TABLE 3.5 Multidrug efflux pumps^a

MexAB OprM	<i>Pseudomonas aeruginosa</i>	Chloramphenicol, β -lactams, fluoroquinolones, tetracycline

^aSummarized from Paulsen *et al.* (1996).

efflux proteins exchange a proton for a tetracycline-acylation complex against a concentration gradient. The other major mechanism for tetracycline resistance is target protection. Ribosome protection is conferred by a 72.5-kDa cytoplasmic protein. Sequence analysis has shown regions with a high degree of homology to elongation factors Tu and G (Taylor and Chau, 1996; Sanchez-Pescador *et al.*, 1988).

Every cloud has its silver lining, and the analysis of the *tetA* operon and its regulation by a modulation of a repressor-operator interaction has provided an exquisitely controllable gene expression system for eukaryotic cells. A number of genes in a variety of cell lines have

been placed under the control of the tetracycline-regulated *tetA* promoter with the result that transcription can be activated on the addition of the drug.

c. Chloramphenicol

Chloramphenicol acts on the 50 S ribosomal subunit to inhibit the peptidyl transferase reaction in protein synthesis. It is an effective broad-spectrum antibiotic, is inexpensive to produce, and is employed extensively in the Third World for the treatment of a variety of gram-negative pathogens (*Salmonella*, *Vibrio*, and *Rickettsia*). Liberal over-the-counter availability in many countries ensures strong selection pressure for the maintenance of chloramphenicol resistance. The number of indications for which chloramphenicol is the drug of choice has declined rapidly because of chronic toxicity, namely, depression of bone marrow function leading to blood disorders such as aplastic anemia. Thus, though chloramphenicol resistance determinants are widespread, their presence is not of major consequence from a therapeutic standpoint in Europe and North America.

Chloramphenicol acetyltransferases (CATs) are widely distributed among bacterial pathogens of all genera. This group of enzymes has been analyzed in great detail by Shaw and collaborators (Shaw, 1984; Murray and Shaw, 1997); at least a dozen breeds of CAT genes encoding similar but not identical acetyltransferases have been identified (Bannam and Rood, 1991; Parent and Roy, 1992). As with the aminoglycoside-modifying enzymes, the CAT genes are (presumably) of independent derivation, because they cannot be linked by a small number of point mutations to a single ancestral gene. Potential origins for the CAT family have yet to be clearly identified. The type I CAT (encoded by transposon Tn9) has two activities: in addition to catalyzing the acylation of chloramphenicol, the protein forms a tight stoichiometric complex with the steroidal antibiotic fusidic acid (Bennett and Chopra, 1993); thus sequestered, the latter antibiotic is ineffective. This is the only plasmid-determined resistance to fusidic acid that has been characterized. Notwithstanding their different structures, the two antibiotics bind competitively to the enzyme; interestingly, both chloramphenicol and fusidic acid exert their antibiotic action through inhibition of bacteria protein synthesis (fusidic acid blocks the translocation of the ribosome along the mRNA). Hence, the type I CAT is bifunctional, determining resistance to two structurally related antibiotics by distinct mechanisms.

Given our understanding of the basic biochemistry of the drug and knowledge of the mechanism of chloramphenicol resistance (Day and Shaw, 1992), it is

surprising that more effort has not been put into rational drug design of chloramphenicol analogs of lower toxicity that would be active against resistant strains. Shaw's group has studied the CAT protein extensively; the 3-D structure of the protein is known, and site-directed mutagenesis has been used to establish the kinetics of the reaction mechanism (Murray and Shaw, 1997). Fluorinated analogs of chloramphenicol with reduced substrate activity for CAT have been produced but have not been afforded extensive clinical study (Cannon *et al.*, 1990). The antibiotic has an excellent inhibitory spectrum: might it be possible to use fusidic acid analogs to inhibit chloramphenicol acylation?

Although the CAT mechanism is the most common form of chloramphenicol resistance, a second type causing the active efflux of chloramphenicol from *Pseudomonas* cells has been described (Bissonnette *et al.*, 1991). The *cml* determinant is encoded on integrons (see Section IV.A) and, like the tetracycline efflux pump, is a member of the MF family of efflux systems (see Section II.B.2, and Table 3.5). The presence of the cloned *cml* gene in *E. coli* leads to, in addition to active pumping of the drug from the cell, a reduction in outer membrane permeability to chloramphenicol by repressing the synthesis of a major porin protein (Bissonnette *et al.*, 1991). This effect has also been reported for the homolog of the *cml* gene in *Haemophilus influenzae*, a major causative agent of meningitis.

d. Macrolides, lincosamides, and streptogramins

The macrolide–lincosamide–streptogramin (MLS) group of antibiotics have been used principally for the treatment of infections caused by gram-positive bacteria. The macrolides, especially erythromycin and its derivatives, have been used extensively and may be employed for the treatment of methicillin-resistant *Staphylococcus aureus* (MRSA), although the multiple drug resistance of the latter often includes the MLS class. Extensive studies on the mechanism of action of erythromycin identify the peptidyltransferase center as the target of the drug although there are clearly some subtleties in mechanism that remain to be resolved.

The principal mechanism of resistance to macrolide antibiotics involves methylation of the 23 S rRNA of the host giving the *erm*^R phenotype. In clinical isolates, enzymatic modification of rRNA, rendering the ribosome refractory to inhibition, is the most prevalent mechanism and, worldwide, compromises the use of this class of antibiotic in the treatment of gram-positive infections (Leclercq and Courvalin, 1991). Mutation of rRNA has also been shown to be important in some clinical situations: nucleotide sequence comparisons of clarithromycin-resistant clinical isolates

of *Helicobacter pylori* revealed that all resistant isolates had a single base pair mutation in the 23 S rRNA (Debets-Ossenkopp *et al.*, 1996). In addition, a number of different mechanisms for the covalent modification of the MLS group have been described. For example, O-phosphorylation of erythromycin has been identified in a number of bacterial isolates (O'Hara *et al.*, 1989), and hydrolytic cleavage of the lactone ring of this class of antibiotics has also been described. The lincosamides (lincomycin and clindamycin) have been shown to be inactivated by enzymatic O-nucleotidylation in gram-positive bacteria. Macrolides are also inactivated by esterases and acetyltransferases. For macrolides and lincosamides and the related streptogramins (the MLS group) (Arthur *et al.*, 1987; Brisson-Noël *et al.*, 1988), the latter forms of antibiotic inactivation seem (for the moment) to be a relatively minor mechanism of resistance.

The macrolide antibiotics, especially the erythromycin group (14-membered lactones), contain a number of semisynthetic derivatives that have improved pharmacological characteristics. This includes activity against some resistant strains: however, no derivative has been found with effective potency against *erm*^R strains. The 23 S rRNA methyltransferases from pathogenic gram-positive cocci remain the most significant problem. To our knowledge, no useful inhibitor of these enzymes has been identified; with the availability of ample quantities of the purified enzymes it would not be surprising if rationally designed, specific inhibitors of some of the *erm* methyltransferases may eventually be developed.

The control of expression of the *erm* methyltransferases has been studied extensively by Weisblum and by Dubnau and their colleagues (Weisblum, 1995; Monod *et al.*, 1987). The majority of the resistant strains possess inducible resistance which is due to a novel posttranslational process in which the ribosome stalls on a 5'-leader sequence in the presence of low concentrations of antibiotic. The biochemistry of this process has been analyzed extensively. Point mutations or deletions that disrupt the secondary structure of the leader protein sequence generate constitutive expression, and such mutants have been identified clinically. These strains are resistant to the majority of MLS antibiotics. The regulation of antibiotic resistance gene expression takes many forms (see tetracycline and vancomycin for other examples); the leader-control process seen with the *erm* methylases is reminiscent of the control of amino acid biosynthesis by attenuation, which has been extensively studied. One cannot help but marvel at the simplicity and "cheapness" of this form of control of gene expression—all that is required is a few extra bases flanking

the 5' end of the gene with no requirement of additional regulatory genes.

The streptogramins (especially virginiamycins) contain two components, a macrocyclic lactone and a depsipeptide which have synergistic activity (one such combination has been named Synercid®). These compounds have long been used as animal feed additives with the result that bacteria resistant to the MLS class of antibiotics are commonly found in the flora of farm animals. This nontherapeutic application is likely to compromise the newer MLS antibiotics being developed for human therapy. For example, derivatives of the pristinamycins (quinupristin and dalfopristin) will shortly be recommended for the treatment of vancomycin-resistant enterococci, against which they have potent activity. Regrettably, due to animal applications of MLS antibiotics a significant gene pool of resistance determinants is already widely disseminated.

e. Mupirocin

Mupirocin is an example of how quickly resistance can develop to a new antibiotic. Introduced in 1985, it has been used solely as a topical treatment for staphylococcal skin infections and as a nasal spray against commensal MRSA. Mupirocin, also known as pseudomonic acid A, is produced by the gram-negative bacterium *Pseudomonas fluorescens*. It acts by inhibiting isoleucyl-tRNA synthetase, which results in the depletion of charged tRNA Ile, amino acid starvation, and ultimately the stringent response. The first reports of mupirocin resistance (MuR) appeared in 1987; while not yet a widespread problem, the Mu^R phenotype in coagulase-negative staphylococci and MRSA among others is emerging in many hospitals all over the world (Cookson, 1995; Zakrzewska-Bode *et al.*, 1995; Udo *et al.*, 1994). Resistance is due to the plasmid-encoded *mupA* gene, a mupirocin-resistant isoleucyl-tRNA synthetase (Noble *et al.*, 1988). Transfer has been demonstrated by filter mating and probably accounts for the rapid spread of resistance (Rahman *et al.*, 1993). An analysis of plasmids from clinical isolates of *S. aureus* has shown that mupirocin resistance can be found on multiple resistance, high copy number plasmids (Needham *et al.*, 1994).

2. Cell wall synthesis

The synthesis and integrity of the bacterial cell wall have been the focus of much attention as targets for antimicrobial agents. This is principally because this structure and its biosynthesis is unique to bacteria and also because inhibitors of cell wall synthesis are usually bacteriocidal.

a. β -Lactams

In the years following the introduction of the β -lactam antibiotics (penicillins and cephalosporins) for the treatment of gram-negative and gram-positive infections, there has been a constant tug-of-war between the pharmaceutical industry and the bacterial population: the one to produce a novel β -lactam effective against the current epidemic of resistant bugs in hospitals, and the other to develop resistance to the newest "wonder" drug.

The role of mutation is especially important in the evolution or expansion of resistance in the case of β -lactams. In a 1992 review Neu showed the "phylogeny" of development of β -lactam antibiotics in response to the evolution of bacterial resistance to this class of antibiotics (Neu, 1992). Of the several known mechanisms of resistance to the β -lactam antibiotics (Table 3.1), the most elusive target is hydrolytic inactivation by β -lactamases. A single base change in the gene for a β -lactamase can change the substrate specificity of the enzyme (Jacoby and Archer, 1991). Such changes occur frequently, especially in the Enterobacteriaceae, and it is frightening to realize that one single base change in a gene encoding a bacterial β -lactamase may render useless \$100 million worth of pharmaceutical research effort.

The cycle of natural protein engineering in response to changing antibiotic-selection pressure has been demonstrated especially for the TEM β -lactamase (penicillinase and cephalosporinase) genes. The parental genes appear to originate from a variety of different (and unknown) sources (Couture *et al.*, 1992). The β -lactamase families differ by a substantial number of amino acids, as is the case for other antibiotic resistance genes. Sequential expansion of their substrate range to accommodate newly introduced β -lactam antibiotics is a special case and occurs by a series of point mutations at different sites within the gene that change the functional interactions between the enzyme and its β -lactam substrate. More than 30 of the so-called extended-spectrum β -lactamases have been identified (and more will come). The fact that the β -lactamase genes so readily undergo mutational alterations in substrate recognition could have several explanations, one being that the β -lactamases, like the related proteases, have a single active site that does not require interaction with any cofactors. Other antibiotic-modifying enzymes often have two active binding sites. The pharmacokinetic characteristics of the different classes of antibiotics (e.g. dose regimen, active concentration, and route of excretion) also may favor the pathway of mutational alteration in the development of resistance. One aspect of the mutational variations of the β -lactamase genes

might involve the presence of mutator genes on the R plasmids in the bacterial hosts (LeClerc *et al.*, 1996). These genes increase mutation frequency several-fold and could explain the facile evolution of the TEM-based enzymes. This characteristic of bacterial pathogens has received comparatively little study.

As one approach to counteracting the destructive activity of β -lactamases, a series of effective inhibitors of these enzymes has been employed. The inhibitors are structural analogs of β -lactams that are, in most cases, dead-end irreversible inhibitors of the enzyme. Several have been used in combination with a β -lactam antibiotic for the treatment of infections from resistant microbes, for example, the successful combination of amoxicillin (antibiotic) and clavulanic acid (inhibitor). However, the wily microbes are gaining the upper hand once again by producing mutant β -lactamases that not only are capable of hydrolyzing the antibiotic but concomitantly become refractory to inhibition (Blazquez *et al.*, 1993).

In addition to active site mutation, other changes in β -lactamase genes have evolved in response to continued β -lactam use. In some cases, increased resistance results from increased expression of the gene through an upregulating promoter mutation (Chen and Clowes, 1987; Mabilat *et al.*, 1990); alternatively, chromosomal β -lactamase genes can be overexpressed in highly resistant strains as a result of other changes in transcriptional regulation (Honoré *et al.*, 1986).

Drug inactivation is not the only mechanism of resistance to the β -lactams. In fact, mutations that alter access to the target (penicillin binding proteins, pbp) of the drug through porin channels have been widely reported (Nikaido, 1994). Methicillin resistance in *S. aureus* (MRSA) is due to an unusual genetic complex which replaces the normal pbp2 with the penicillin refractory pbp2A. The origin of this resistance determinant is unknown, but the consequences of the clonal distribution of MRSA is well documented. It would appear that most MRSA are close relatives of a small number of parental derivatives that have been disseminated by international travel. Alterations of other pbp's in different bacterial pathogens have been responsible for widespread resistance to β -lactam antibiotics; in the case of *Streptococcus pneumoniae* and *Neisseria gonorrhoeae* this has occurred by interspecific recombination leading to the formation of mosaic genes that produce pbps with markedly reduced affinity for the drugs.

b. Glycopeptides

The glycopeptide antibiotics, vancomycin and teicho-planin, were first discovered in the 1950s but have

only come into prominence since the late 1980s, being the only available class of antibiotic effective for the treatment of MRSA and methicillin-resistant enterococci (MRE). However, numerous outbreaks of vancomycin-resistant enterococci (VRE) have been reported in hospitals around the world (VRE are essentially untreatable by any approved antibiotic), and there is great concern that vancomycin-resistance determinants will be transferred to pathogenic staphylococci; the resulting methicillin, vancomycin resistant *S. aureus* (MVRSA) will be the "Superbug," the "Andromeda" strain that infectious disease experts fear most (at least according to the newspapers). The glycopeptides block cell wall synthesis by binding to the peptidoglycan precursor dipeptide D-alanyl-D-alanine (D-Ala-D-Ala) and preventing its incorporation into the macromolecular structure of the cell wall. The most common type of resistance is the vanA type found principally in *Enterococcus faecalis* (Walsh *et al.*, 1996; Arthur *et al.*, 1996). Resistance due to the VanA phenotype results from the substitution of the depsipeptide D-alanyl-D-lactate (D-Ala-D-Lac) for D-Ala-D-Ala residues, thereby reducing the binding of the antibiotic by eliminating a key hydrogen bond in the D-Ala-D-Ala complex. The introduction of D-Lac is encoded by the nine genes of the VanA cluster and is associated with a mechanism to prevent the formation of native D-Ala-D-Ala containing peptide in the same host; thus, the resistance is dominant. Vancomycin resistance is inducible by a two-component regulatory system; the inducers are not the antibiotics, but rather the accumulated peptidoglycan fragments produced by the initial inhibitory action of the glycopeptides. The VanA cluster is normally found on a conjugative transposon related to Tn1546, and it is probably responsible for the widespread dissemination of glycopeptide resistance among the enterococci. A plasmid carrying the VanA resistance determinants has been transferred from enterococci to staphylococci under laboratory conditions (Noble *et al.*, 1992), and there is apprehension that this will occur in clinical circumstances. Regrettably a glycopeptide antibiotic, avoparcin, has been employed extensively as a feed additive for chickens and pigs in certain European countries. This has led to the appearance of a high proportion glycopeptide-resistant enterococci in natural populations. This feeding practice has now been banned by the European Union (EU), but is it too late? Only time will tell.

c. Fosfomycin

A widely used mechanism for the detoxification of cell poisons in eukaryotes is the formation of glutathione adducts; for example, this mechanism is

commonly used for herbicide detoxification in plants (Timmermann, 1988). However, in spite of the fact that many microbes generate large quantities of this important thiol, only one example of an antibiotic resistance mechanism of this type has so far been identified in bacteria, namely, that of fosfomycin. Fosfomycin, produced by a streptomycete, is an analog of phosphoenol pyruvate and interferes with bacterial cell wall synthesis by inhibiting the formation of *N*-acetylmuramic acid, a unique component of bacterial cell walls. It is employed in the treatment of sepsis, both alone and in combination with other antimicrobial agents. In gram-negative bacteria transmissible resistance is due to a plasmid-encoded glutathione *S*-transferase that catalyzes the formation of an inactive fosfomycin–glutathione adduct (Arca *et al.*, 1990). Two independent genes for fosfomycin resistance have been cloned and sequenced, one from *Serratia marcescens* (Suárez and Mendoza, 1991) and the other from *Staphylococcus aureus* (Zilhao and Courvalin, 1990); the two genes are unrelated at the sequence level. It is unlikely that the gram-positive gene encodes an enzyme involved in the production of a glutathione adduct, because *S. aureus* does not contain glutathione!

3. DNA and RNA synthesis

Nucleic acid metabolism has attracted much attention as a potential target for antimicrobial drugs; the strategy of hitting at the “heart” of the microbe seemed the most likely to lead to effective bactericidal agents. Unfortunately, the ubiquity of DNA and RNA and the failure to identify discriminating target differences in the biosynthetic enzymes made this search unproductive until relatively recently when the fluoroquinolones (a class of synthetic drugs with no known natural analogs) were introduced. However, resistance mechanisms were not long in appearing, and the fluoroquinolones instead of being the “superdrugs” needed, are already limited by resistance.

a. Fluoroquinolones

Nalidixic acid, the prototype quinolone antibiotic discovered in 1962, had limited use, principally for urinary tract infections caused by gram-negative bacteria. Resistance developed by mutation, and the nal^R phenotype proved to be the first useful marker for *gyrA* the gene encoding the A subunit of DNA gyrase (topoisomerase I). The development of resistance to nalidixic acid occurred solely by this type of mutation, and plasmid-determined resistance has never been reliably identified. This is not surprising, given that nalidixic acid is a purely synthetic chemical and no natural analog has been identified.

In the late 1970s, the first fluoroquinolone antimicrobials were introduced; these proved vastly superior to nalidixic acid and are among the most potent antimicrobial agents known. A number of fluoroquinolone antibiotics have now been introduced as anti-infectives and most show good, broad-spectrum activity. In laboratory studies, mutations to high-level resistance occurred at relatively low frequency, and genetic studies identified a number of different DNA replication-associated targets. As with nalidixic acid, topoisomerase I is the principal target, but other targets associated with bacterial DNA replication which give the FQ^R phenotype have been identified in different bacterial species. In clinical use, resistance to the newer fluoroquinolones has been found to develop quite rapidly as a result of one or more mutations. In addition to target mutation, active efflux of the drug is also an important mechanism of resistance; for example, the *norA* mutation identifies a multiple drug resistance (*mdr*) system in *S. aureus* (see Section II.B.2 and Table 3.5). Strains resistant to high levels of the drug have been identified frequently during the course of treatment especially with *P. aeruginosa* and *S. aureus* infections. Resistance is due to multiple mutations leading to increased efflux and alteration of components of the DNA synthetic apparatus. Clonal dissemination of FQ^R strains appears to be quite common in nosocomial *P. aeruginosa* infections. No plasmid-mediated resistance to fluoroquinolones has been identified to date, although possible mechanisms leading to dominant resistance genes can be envisaged.

b. Rifampicin

Rifampicin is the only inhibitor of bacterial (and mitochondrial) RNA polymerases that has ever been used in the treatment of infectious disease. Mutations in the gene encoding the β subunit of RNA polymerase (*rpoB*) give high level resistance to the drug; the study of these mutations has provided important information on the structure and function of the RNA polymerase proteins in bacteria. Rifampicin is used in the treatment of gram-positive bacteria and is effective against mycobacterial and staphylococcal infections. Because it is lipophilic and thus diffuses rapidly across the hydrophobic cell envelope of mycobacteria, rifampicin is one of the frontline drugs for the treatment of tuberculosis and leprosy. However, the appearance of resistant strains as a result of *rpoB* mutations is quite common in multiple drug-resistant strains (Cole, 1994). In addition, inactivation of rifampicin in fast growing mycobacterial strains by phosphorylation, glucosylation, and ribosylation has been reported (Dabbs *et al.*, 1995).

4. Folic acid biosynthesis

As the above discussion illustrates, the biosynthesis and function of cellular macromolecules are the principal targets for the majority of antimicrobial agents. However, interference with the activity of enzymes involved in intermediary metabolism is also an effective strategy. Although many potential antimicrobial targets have been identified and tested, to date only folic acid biosynthesis has been successfully exploited in the development of useful drugs.

Folic acid is involved in the transfer of one-carbon groups utilized in the synthesis and metabolism of amino acids such as methionine and glycine and in the nucleotide precursors adenine, guanine, and thymine. Folic acid is converted in two reduction steps to tetrahydrofolate (FH₄), which serves as the intermediate carrier of hydroxymethyl, formyl, or methyl groups in a large number of enzymatic reactions in which "one-carbon" groups are transferred from one metabolite to another or are interconverted. The synthetic antibacterial agents sulfonamides and trimethoprim inhibit specific steps in the biosynthesis of FH₄. The current state of resistance to sulfonamides and trimethoprim in major bacterial pathogens and the mechanisms of sulfonamide and trimethoprim resistance have been reviewed (Huovinen *et al.*, 1995).

a. Sulfonamides

The sulfonamides were first discovered in 1932 and introduced into clinical practice in the late 1930s. They have a wide spectrum of activity and have been used in urinary tract infections due to the Enterobacteriaceae, in respiratory tract infections due to *Streptococcus pneumoniae* and *Haemophilus influenzae*, in skin infections due to *S. aureus*, and in gastrointestinal tract infections due to *E. coli* and *Shigella* spp. The wide range of clinical indications and low production costs maintain the popularity of the sulfonamides in Third World countries. The enzyme dihydropteroate synthase (DHPS) catalyzes the formation of dihydropteroyl acid, the immediate precursor of dihydrofolic acid. DHPS found in bacteria and some protozoan parasites, but not in human cells, is the target of sulfonamides. These drugs are structural analogs of *p*-aminobenzoic acid, the normal substrate of DHPS, and act as competitive inhibitors for the enzyme, thus blocking folic acid biosynthesis in bacterial cells. A large number of sulfonamides have been synthesized that show wide variations in therapeutic activity! One class, the dapsones, remains an effective anti-leprosy drug.

b. Trimethoprim

Trimethoprim was first introduced in 1962, and since 1968 it has been used (often in combination with sulfonamides due to a supposed synergistic effect) for numerous clinical indications. Like the sulfonamides, trimethoprim has a wide spectrum of activity and low cost. The target is the enzyme dihydrofolate reductase (DHFR), which is essential in all living cells. Trimethoprim is a structural analog of dihydrofolic acid and acts as a competitive inhibitor of the reductase. The human DHFR is naturally resistant to trimethoprim, which is the basis for its use.

Resistance has been reported to both trimethoprim and sulfonamides since their respective introductions into clinical practice. Although the principal form of resistance is plasmid mediated, a clinical isolate of *E. coli* was described in which the chromosomal DFHR was overproduced several hundredfold, leading to very high trimethoprim resistance (minimum inhibitory concentration >1 g/l). Sul^R and Tmp^R strains carry plasmid-encoded *dhps* and *dhfr* genes that may be up to 100 times less susceptible to the inhibitors. Extensive genetic and enzymatic studies, principally by Sköld and collaborators, have characterized resistance in the Enterobacteriaceae. The *sul* gene is part of the 3' conserved region of integron structures and may have been the first resistance determinant acquired (see Section IV.A). Less information is available for resistant gram-positive pathogens. Nonetheless, the origins of Sul^R and Tmp^R genes remains a mystery.

B. Broad-spectrum resistance systems

In the first part of this section, we examined bacterial targets for antibiotic activity and mechanisms that specifically provide resistance to those antibiotics. The mechanisms included modification of the target (e.g. vancomycin resistance), modification of the antibiotic (e.g. aminoglycoside methyltransferases), overproduction of the target (e.g. trimethoprim resistance), and extrusion of the drug from the cell (e.g. TetA-type tetracycline resistance). However, even as the first antimicrobial agents were being tested, researchers noticed "intrinsic" differences in sensitivity among the target organisms to a wide range of compounds.

1. Membranes and cell surfaces

Initially, intrinsic differences in resistance to antibiotics and other chemotherapeutic agents were attributed to structures such as the gram-negative outer membrane and the mycobacterial cell surface. Intrinsic drug resistance in mycobacteria has been reviewed by

Nikaido and collaborators (Jarlier and Nikaido, 1994). They suggest that lipophilic molecules are slowed by the low fluidity of the lipid bilayer surrounding the cell wall and that hydrophobic molecules enter the mycobacterial cell slowly because the porins are inefficient and few in number. They note that although these surface features strongly contribute the high level of natural resistance in mycobacteria, other factors are also involved such as pbps with low affinity for penicillin and the presence of β -lactamases.

2. Multidrug efflux pumps

A cell has a number of different ways to export material across its membrane. All of them involve the expenditure of energy. The most well-characterized multiple drug resistance pumps in mammalian cells are the ABC (ATP binding cassette) transporters. In bacteria, the ABC transporters are primarily seen in the translocation of virulence factors such as hemolysin in *E. coli* and cyclolysin in *Bordetella pertussis*. A second type of active export system has been characterized in which the energy to drive the pump comes from the proton motive force (PMF) of the transmembrane electrochemical proton gradient. These multidrug efflux systems have been the subject of a number of reviews (Lewis, 1994; Nikaido, 1996; Paulsen *et al.*, 1996). There are three families of PMF multidrug efflux pumps: the major facilitator superfamily (MFS), the staphylococcal (or small) multidrug resistance (SMR) family, and the resistance/nodulation/cell division (RND) family. Table 3.5 lists examples from each of these families and the types of compounds they pump out of the cell. In addition to these multisubstrate pumps, proton motive force efflux pumps for specific antibiotic resistance, such as the TetK and TetL (MFS-type) pumps, have also been described (see Section II.A.1.b).

The Acr multidrug efflux pump found in *E. coli* is one of the most well characterized of the RND-type pumps. Expression of the Acr efflux pump is controlled by the *marA* protein. The multiple antibiotic resistance (*mar*) phenotype was first described in 1983 by Levy and co-workers when they plated *E. coli* on medium containing either tetracycline or chloramphenicol and obtained mutants that were also resistant to the other antibiotic. Further analysis showed that these mutants had additional resistances to β -lactams, puromycin, rifampicin, and nalidixic acid. The most striking aspect of this multiple drug resistance phenotype was the wide range of structurally unrelated compounds with which it was observed. Subsequent studies have found that the *mar* phenotype is part of a complex stress response system which includes the superoxide response locus *soxRS* (Miller and Sulavik,

1996). Rather than encoding the structural components responsible for the *mar* phenotype, the *mar* locus encodes a regulatory system. The *marA* protein is a positive regulator which controls expression of at least two loci, the *acr* locus, which encodes the genes for a multidrug efflux pump, and the *micF* locus, which encodes an antisense repressor of the outer membrane protein *ompF*. Expression from the *mar* locus is tightly controlled by the first gene in the operon, *marR*, which encodes a repressor protein (Miller and Sulavik, 1996).

As noted above, the *mar* locus is part of a complex stress response system. Levy and co-workers (Goldman *et al.*, 1996) have reported that mutations of the *marR* repressor protein protected *E. coli* from rapid killing by fluoroquinolones. They hypothesize that such protection may allow cells time to develop mutations that lead to higher levels of fluoroquinolone resistance, and may thus explain the increasing frequency of occurrence of resistant clinical isolates. Such mutations have been found among clinical strains of fluoroquinolone-resistant *E. coli*, suggesting that mutations at the *mar* locus may be the first step in clinically significant fluoroquinolone resistance. The latter may have been the case for all clinically significant antibiotic resistance: a mutational event leading to a low-level increase in drug efflux, followed by the acquisition of a heterologous resistance determinant, leading to high-level antibiotic resistance.

3. Other types of natural resistance

Other types of natural resistance in bacteria will depend on the organism and the drug in question. For example, three species of enterococci, *Enterococcus gallinarum*, *E. casseliflavus*, and *E. flavescens*, produce peptidoglycan precursors which end in D-serine residues and are intrinsically resistant to low levels of vancomycin. Similarly, genera from the lactic acid bacteria *Lactobacillus*, *Leuconostoc*, and *Pediococcus* are resistant to high levels of glycopeptides because their cell wall precursors end with D-lactate. As noted above, mycobacteria species have pbps which have a low affinity for penicillin. In addition, some mycobacteria have been reported to have ribosomes that have a lower affinity for macrolides than the ribosomes of *S. aureus* (Jarlier and Nikaido, 1994).

III. GENE TRANSFER

All available evidence suggests that the acquisition and dissemination of antibiotic resistance genes in bacterial pathogens has occurred since the late 1940s.

The best support for this notion comes from studies of Hughes and Datta (Datta and Hughes, 1983; Hughes and Datta, 1983) who examined the "Murray Collection," a collection of (mostly) gram-negative pathogens obtained from clinical specimens in the pre-antibiotic era. None of these strains show evidence of resistance to antibiotics in current use. Given the critical role of gene exchange in bacterial evolution, it is self-evident that extensive interspecific and intergeneric gene transfer must have occurred during the golden age of antibiotics. This subject has been reviewed many times, and a variety of mechanisms of gene transfer have been invoked in the process of resistance determinant acquisition and dispersion (see Table 3.6) and characterized in laboratory studies. It can be assumed that these (and probably other processes) all occur in nature.

A. Transduction

Transduction is the exchange of bacterial genes mediated by bacteriophage, or phage. When a phage infects a cell, the phage genes direct the takeover of the host DNA and protein synthesizing machinery so that new phage particles can be made. Transducing particles are formed when plasmid DNA or fragments of host chromosomal DNA are erroneously packaged into phage particles during the replication process. Transducing particles (those carrying nonphage DNA) are included when phage are liberated from the infected cell to encounter another host and begin the next round of infection. Although there are many laboratory studies of transduction of antibiotic resistance, this mechanism has been considered less important in the dissemination of antibiotic resistance genes because phage generally have limited host ranges; they can infect only members of the same or closely related species, and the size of DNA transferred does not usually exceed 50 kb. However, phage of extraordinarily broad host specificity have been described. For example, phage PRR1 and PRD1 will infect any gram-negative bacterium containing the resistance plasmid RP1 (Olsen and Shipley, 1973; Olsen *et al.*, 1974) and could, in principle, transfer genetic information between unrelated bacterial species. Transduction has been documented in at least 60 species of bacteria found in a wide variety of environments (Kokjohn, 1989). Although the actual level of intraspecies and interspecies transduction are unknown, the potential for transductional gene exchange is likely to be universal among the eubacteria. A study of the presence of bacteriophage in aquatic environments has shown that there may be as many as 108 phage particles per milliliter (Bergh *et al.*,

1989); the authors calculate that at such concentrations one-third of the total bacterial population is subject to phage attack every 24 h. In transduction the DNA is protected from degradation within the phage particle, and Stotzky has suggested that transduction may be as important as conjugation or transformation as a mechanism of gene transfer in natural habitats (Stotzky, 1989).

B. Conjugation

Conjugation is the process in which DNA is transferred during cell-to-cell contact. It has long been considered the most important mechanism for the dissemination of antibiotic resistance genes. During an epidemic of dysentery in Japan in the late 1950s increasing numbers of *Shigella dysenteriae* strains were isolated that were resistant to up to four antibiotics simultaneously. It soon became clear that the emergence of multiply resistant strains could not be attributed to mutation. Furthermore, both sensitive and resistant *Shigella* could be isolated from a single patient, and the *Shigella* sp. and *E. coli* obtained from the same patients often exhibited the same multiple resistance patterns. These findings led to the discovery of resistance transfer factors and were also an early indication of the contribution of conjugative transfer to the natural evolution of new bacterial phenotypes.

In addition to plasmid-mediated conjugal transfer, another form of conjugation has been reported to take place in gram-positive organisms. Conjugative transposons were first reported in *S. pneumoniae* when the transfer of antibiotic resistance determinants occurred in the absence of plasmids (Shoemaker *et al.*, 1980). Salyers has suggested that conjugative transposons may be more important than conjugative plasmids in broad host-range gene transfer between some species of bacteria (Salyers, 1993). Conjugative transposons are not considered typical transposons (Scott, 1992). As of 1993, three different families of conjugative transposons had been found: (a) the Tn916 family (originally found in streptococci but now known also to occur in gram-negative bacteria such as *Campylobacter*) (Salyers, 1993); (b) the *S. pneumoniae* family; and (c) *Bacteroides* family. Conjugative transposons range in size from 15 to 150 kb, and, in addition to other resistance genes, most encode tetracycline-resistance determinants (e.g. Tn916 encodes the TetM determinant, and TetQ (Salyers, 1993) is found on the conjugative transposon from the *Bacteroides* group).

Does conjugation take place in the environment? The ideal site for gene transfer is the warm, wet, nutrient-abundant environment of the mammalian intestinal tract with its associated high concentration of bacteria.

TABLE 3.6 Gene transfer processes

Process	Components	Required genetic determinants		Observed in		DNA form ^b	DNA size	Host range	Comments
		Donor	Recipient ^a	Laboratory	Nature				
Conjugation	Cell/cell	Transfer genes	May require receptor	+	+	ss	≥4 Mb	Very broad interspecific, intergeneric	Can be of very high efficiency; can reduce problem of restriction in recipient
Fusion	Cell/cell	?	?	+(rare)	-	ds	Unlimited	?	Likely to involve partners with damaged wall or membranes (protoplasts or spheroplasts)
Transduction	Bacteriophage /cell	Phage receptor	Phage receptor	+	+	ds	≤50 kb	Limited to closely related species	Very efficient
Transformation ^c	DNA/cell	-	a.Competence determinants b.Chemical or physical changes	+	+	ss/ds	≤50 kb	Very broad	Chemically and electrically induced competence required; efficiency variable

^aAll DNA exchange processes are subject to the negative effects of restriction (nuclease action) in the recipient.

^bAll processes, in principle, may take place with transfer of intact plasmids, chromosomes, or linear fragments. The requirement for recombination in the recipient depends on the nature of transferred DNA and its properties. ss, Single stranded; ds, double stranded.

^cMany bacterial species are genetically non-competent, but may be converted to a competent state by laboratory processes. Electrotransformation is a good example.

The resident microflora is believed to serve as a reservoir for genes encoding antibiotic resistance which could be transferred not only to other members of this diverse bacterial population, but also to transient colonizers of the intestine, such as soil or water microbes or human pathogens. Using oligonucleotide probes having DNA sequence similarity to the hyper-variable regions of the TetQ determinant, Salyers and co-workers provided evidence that gene transfer between species of *Bacteroides*, one of the predominant genera of the human intestine, and *Prevotella* sp., one of the predominant genera of livestock rumen, has taken place under physiological conditions (Nikolich *et al.*, 1994).

C. Transformation

Natural transformation is a physiological process characteristic of many bacterial species in which the cell takes up and expresses exogenous DNA. Although natural transformation has been reported to occur only in a limited number of genera, these include many pathogenic taxa such as *Haemophilus*, *Mycobacterium*, *Streptococcus*, *Neisseria*, *Pseudomonas*, and *Vibrio* (Stewart, 1989). Initial studies suggested that natural transformation in some of these genera was limited to DNA from that particular species. For example, an 11-bb recognition sequence permits *Haemophilus influenzae* to take up its own DNA preferentially compared to heterologous DNAs (Kahn and Smith, 1986). Given such specificity one could ask if natural transformation is an important mechanism in the transfer of antibiotic resistance genes. Spratt and co-workers have reported the transfer of penicillin resistance between *S. pneumoniae* and *N. gonorrhoeae* by transformation. Further, Roberts reported that when the TetB determinant (which is conferred by conjugation in other gram-negative groups) is present in *Haemophilus* species and highly tetracycline-resistant *Moraxella catarrhalis*, it is disseminated by transformation (Roberts *et al.*, 1991).

D. General considerations

There is a world of difference between laboratory and environmental studies. While the isolation of pure cultures is an important component of bacterial strain identification, the use of purified bacterial species in gene transfer studies does little to identify the process and probably bears no relationship to the processes of genetic exchange that take place in the complex microbial populations of the gastrointestinal tract (for example). When antibiotic-resistant bacteria are isolated from diseased tissue and identified as the responsible pathogen, this is the identification of the final product of a complex and poorly understood environmental

system. Although gene exchange may under normal circumstances be rare in stable microbial microcosms, the intense selective pressure of antibiotic usage is likely to have provoked cascades of antibiotic resistance gene transfer between unrelated microbes. These transfers must involve different biochemical mechanisms during which efficiency is not a critical factor since the survival and multiplication of a small number of resistant progeny suffices to create a clinically problematic situation.

It should be apparent that a great deal of additional study using modern molecular and amplification methods with complex microbial communities is necessary before the parameters of natural antibiotic resistance gene transfer can be defined properly.

IV. EVOLUTION OF RESISTANCE DETERMINANT PLASMIDS

A. The integron model

Studies by Hughes and Datta of plasmids they isolated from the Murray collection (Hughes and Datta, 1983; Datta and Hughes, 1983) suggest that the appearance of resistance genes is a recent event, that is, the multi-resistance plasmids found in pathogens must have been created since the 1940s. What really takes place when a new antimicrobial agent is introduced and plasmid-determined resistance develops within a few years? The most significant component of the process of antibiotic resistance flux in the microbial population is gene pickup, which has now been emulated in the laboratory. Largely due to the studies of Hall and co-workers (Stokes and Hall, 1989; Collis *et al.*, 1993; Recchia and Hall, 1995), we have a good idea of the way in which transposable elements carrying multiple antibiotic resistance genes might be formed. From their studies of the organization of transposable elements, these researchers have identified a key structural constituent of one class of transposon that they named an "integron." The integron is a mobile DNA element with a specific structure consisting of two conserved segments flanking a central region in which "cassettes" that encode functions such as antibiotic resistance can be inserted. The 5' conserved region encodes a site-specific recombinase (integrase) and a strong promoter or promoters that ensure expression of the integrated cassettes. The integrase is responsible for the insertion of antibiotic resistance gene cassettes downstream of the promoter; ribosome binding sites are conveniently provided. More than one promoter sequence exists on the element (Lévesque *et al.*, 1994); transcription initiation is very efficient and functions in

FIGURE 3.1 The general structure of an integron. Integrons consist of a 5' conserved sequence that encodes an integrase and contains promoter sequences (P) responsible for the transcription of inserted gene cassettes. The 3' conserved sequence encodes resistance to sulfonamide drugs (*sul*). The insertion site for gene cassettes (GTTRRRY) is indicated.

both gram-negative and gram-positive bacteria. The 3' conserved region carries a gene for sulfonamide resistance (*sul*) and two open reading frames of unknown function. Probably the ancestral integron, encoded no antibiotic resistance (Fig. 3.1). The ubiquitous presence of *sul* in an element of this type might be surprising, although sulfonamides (see above) have been employed since the mid-1930s and (apart from mercury salts) are the longest used agents for the treatment of infectious diseases. The resistance gene cassettes are integrated into a specific insertion site in the integron. Typically, in the case of Tn21-related transposons, each antibiotic resistance cassette is associated with one of a functional family of closely related, palindromic 59-b elements (or recombination hot spots) located to the 3' side of the resistance gene (Fig. 3.1). Integrase-catalyzed insertion of resistance gene cassettes into resident integrons has been demonstrated (Collis *et al.*, 1993; Martinez and de la Cruz, 1990). In addition, site-specific deletion and rearrangement of the inserted resistance gene cassettes can result from integrase-catalyzed events (Collis and Hall, 1992).

Francia *et al.* (1993) have expanded our understanding of the role of integrons in gene mobilization by showing that the Tn21 integrase can act on secondary target sites at significant frequencies and so permit the fusion of two R plasmids by interaction between the recombination hot spot of one plasmid and a secondary integrase target site on a second plasmid. The secondary sites are characterized by the degenerate pentanucleotide sequence sequence Ga/tTNa/t. Though the details of the mechanism by which new integrons are then generated from the fusion structure are not established, the use of

secondary integration sites could explain how new genes may be inserted into integrons without the necessity for a 59-bp element, as the authors point out.

B. Other multiple resistance plasmids

Analyses of the integron-type transposons provide a good model for the way in which antibiotic resistance genes from various (unknown) sources may be incorporated into an integron by recombination events into mobile elements and hence into bacterial replicons, providing the R plasmids that we know today (Fig. 3.2) (Bissonnette and Roy, 1992). However, in bacterial pathogens a variety of transposable elements have been found that undergo different processes of recombinational excision and insertion. It is not known what evolutionary mechanisms are implicated or whether some form of integron-related structure is present in all cases. For the type of integron found in the Tn21 family, we have plausible models, supported by *in vivo* and *in vitro* studies, to provide a modus operandi by which antibiotic resistance genes were (and are) molecularly cloned in the evolution of R plasmids. A large number of transposable elements carrying virtually all possible combinations of antibiotic resistance genes have been identified (Berg, 1989), and nucleotide sequence analysis of multiresistant integrons shows that the inserted resistance gene cassettes differ markedly in codon usage, indicating that the antibiotic resistance determinants are of diverse origins. Microbes are masters at genetic engineering, and heterologous expression vectors of broad host range in the form of integrons were present in bacteria long before they became vogue for biotechnology companies in the 1980s.

V. ORIGINS

We have described how the majority of antibiotic resistance genes found in microbes have been acquired by their hosts. The important question is, From where did they acquire these genetic determinants? The integron model defines a mechanism by which antibiotic genes can be procured by members of the Enterobacteriaceae and pseudomonads. This mechanism requires the participation of extrinsic resistance genes (or cassettes); however, the origins of these open reading frames are a mystery. The same questions can be applied to any of the resistance genes found in pathogenic bacteria. Available evidence concerning some of the origins is discussed below.

FIGURE 3.2 The diversity of antibiotic resistance integrons. The diagram illustrates the insertion of antibiotic resistance gene cassettes into the basic integron structure (Fig. 3.1). It should be noted that the antibiotic resistance gene cassettes are usually inserted in tandem array and more than five genes may be found in a single integron structure.

A. Antibiotic producers

Antibiotic-producing microbes are the prime suspects for the maintenance of a pool of resistance genes in nature. Any organism producing a toxic molecule must, by definition, possess a mechanism(s) to survive this potentially suicidal situation. Because the majority of antibiotics are produced by bacteria (principally the actinomycete group), one would expect these organisms to have mechanisms of protection against the antibiotics they make. These mechanisms take various forms, and it is significant that the mechanisms of resistance for the known antibiotics in producing organisms and clinical isolates are biochemically identical (see Table 3.7). The gene clusters for antibiotic biosynthesis in producing organisms almost invariably comprise one or more genes that encode resistance to the antibiotic produced. Many of these genes have been cloned and sequenced. Sequence comparisons of the genes from the producer and the clinical isolate often show very high degrees of similarity. Thus, the homologous biochemical mechanisms and the relatedness of the gene sequences support the hypothesis that producing

TABLE 3.7 Resistance determinants with homologs in antibiotic producing organisms

Antibiotic	Mechanism
Penicillins	β -Lactamases
Cephalosporins	Penicillin binding proteins
Aminoglycosides	Phosphotransferases, acetyltransferases, nucleotidyltransferases
Chloramphenicol	Acetyltransferases
Tetracyclines	Ribosomal protection, efflux
Macrolides	rRNA methylation
Streptogramins	Esterases
Lincosamides	Phosphotransferases, acetyltransferases
Phosphonates	Phosphorylation, glutathionylation (?)
Bleomycin	Acetyltransferases, immunity protein

organisms are likely to be the source of most resistance genes. However, other sources of resistance genes are not excluded, and some of these are discussed below.

1. Tetracyclines

The first tangible evidence of resistance gene transfer involving antibiotic-producing streptomycetes in a

clinical setting has come from Pang *et al.* (1994). These researchers analyzed human infections of nontuberculous mycobacteria and *Streptomyces* spp.; the infections did not respond to treatment with tetracyclines. Both microbial species contained resistance genes (*tetK* and *tetL*) known to be the basis of tetracycline resistance in gram-positive bacteria (see Section II.A.1.b on tetracycline resistance determinants). These resistance determinants promote efflux of the drug and are typically transposon-associated. Surprisingly, the mycobacteria and the streptomycetes both had the tetracycline resistance genes (*otrA* and *otrB*) previously identified in the tetracycline-producing strain *Streptomyces rimosus* (Davies, 1992; Doyle *et al.*, 1991). Reciprocally, the streptomycetes had acquired the *tetK* and *tetL* genes. Because the latter are clearly "foreign" genes (*tetK* and *tetL* have a G + C content different from those of streptomycete and mycobacterial chromosomal DNA), they must have been acquired as the result of a recent gene transfer. Although this evidence is consistent with resistance gene transfer between the streptomycetes and other bacteria, it is not known which is donor and which is recipient, nor whether the newly acquired tetracycline resistance genes are plasmid or chromosomally encoded.

2. Aminoglycosides

Covalent modification of their inhibitory biochemical products is very common in antibiotic-producing bacteria. It was the discovery of antibiotic modification as a means of self-protection in the streptomycetes that led to the proposal that antibiotic-producing microbes were the origins of the antibiotic resistance determinants found in other bacteria (Benveniste and Davies, 1973; Walker and Skorvaga, 1973). Support for this hypothesis has been provided by nucleic acid and protein sequence comparisons of aminoglycoside resistance determinants from producing organisms and clinical isolate sources (Shaw, 1984; Davies, 1992). As mentioned above, producing organisms are not the only potential source of antibiotic resistance mechanisms. The proposal that the enzymes that modify aminoglycosides evolved from such "house-keeping" genes as the sugar kinases and acyltransferases has been made by a number of groups (Udou *et al.*, 1989; Shaw *et al.*, 1992; Rather *et al.*, 1993).

3. Macrolides

The principal mechanism of resistance to the macrolide antibiotics involves methylation of the 23 S rRNA of the host. Methylation occurs on a specific adenine residue in the rRNA, and mono- and dimethylation has been described. The *N*-methyltransferase genes

responsible for encoding this protective modification have been studied in detail from both the producing organisms and clinical isolates (Rather *et al.*, 1993). Although no direct transfer of resistance between producer and clinical isolates has been found, the identity of the biochemical mechanism and its regulation make for a compelling evolutionary relationship.

4. Other antibiotics

Perhaps the most straightforward path toward the development of a drug resistance mechanism is via the major facilitator superfamily (MFS; see Section II.B.2) of transporters. The MFS is found in all organisms involved and consists of membrane transport systems involved in the symport, antiport, or uniport of various substrates. Other examples of MFS pumps include sugar uptake systems, phosphate ester/phosphate antiport, and oligosaccharide uptake. One might expect that, in addition to methods for the import of nutrients, a cell would have methods for the removal of harmful substances. The β -lactamases are an interesting case because they are widely distributed among the bacterial kingdom. The ubiquity of β -lactamases suggests that these enzymes may play a part in normal metabolic or synthetic processes, but an essential role has not been shown. Examination of the sequences of β -lactamases by Bush *et al.* (1995) permitted the establishment of extensive phylogenetic relationships, which includes those from microbes employed in the commercial production of β -lactam antibiotics.

In the case of the glycopeptide antibiotics (vancomycin and teichoplanin), resistance in the enterococci is due to the acquisition of a cluster of genes that encode a novel cell wall precursor (see Section II.A.3). A comparison of D-Ala-D-Ala ligases from different sources has shown that the *vanA* gene is dissimilar to the other known genes, suggesting a divergent origin (Arthur *et al.*, 1996). The *vanA* homolog from the producing organism, *Streptomyces toyocaensis*, has been cloned and sequenced. The predicted amino acid sequence was compared with the D-Ala-D-Ala ligase from *Enterococcus* and is greater than 60% similar (G. D. Wright *et al.*, 1997).

B. Unknown origin

There are gaps in our understanding of the origin of resistance determinants. For example, the aminoglycoside nucleotidyltransferases have been found only in clinical isolates and have no known relatives; the potential origins of the chloramphenicol acetyltransferase genes are still unclear (see Section II.A.1.c); and the sources for sulfonamide and trimethoprim

resistance are still not known (see Section II.A.4). There may be examples of "housekeeping" functions of resistance genes. For example, *Providencia stuartii* has a chromosomally encoded aminoglycoside acetyltransferase that may play a role in cell wall peptidoglycan formation (Payie *et al.*, 1995).

VI. MAINTENANCE OF ANTIBIOTIC RESISTANCE

A variety of surveys have indicated that normal healthy humans (who are not pursuing a course of antibiotic therapy) carry antibiotic-resistant enteric species in their intestinal tract; a substantial proportion are found to contain transmissible antibiotic resistance plasmids. Studies have demonstrated that a lack of antibiotic selective pressure, for example, removing antimicrobials from cattle feed, can lead to a gradual decrease in the percentage of resistance genes and resistance bacteria found in a population (Langlois *et al.*, 1986; Hinton *et al.*, 1985).

Although the results of these studies are encouraging, other studies indicate that once resistance cassettes have been developed it is unlikely that they will disappear completely from an environment where antibiotics are routinely used. In a sense "the cat is out of the bag." Chemostat studies (Chao *et al.*, 1983; Hartl *et al.*, 1983) suggest that insertion elements may themselves provide their hosts with a selective advantage independent of the resistance determinants they carry. Roberts has postulated that commensal bacteria can be reservoirs for tetracycline resistance determinants. When bacteria from the urogenital tracts of females who had not taken antibiotics for 2 weeks previously were examined, 82% of the viridans-type streptococci hybridized with at least one Tet determinant (Roberts *et al.*, 1991).

A. Multiple antibiotic resistance and mercury resistance

Although the cooccurrence of antibiotic resistance and resistance to heavy metals such as mercury has long been known, its implications for public health are only now becoming clear. In 1964, the cotransduction of genes encoding resistance to penicillin and mercury by a staphylococcal phage was reported (Richmond and John, 1964). Ten years later it was found that 25% of the antibiotic resistance plasmids isolated from enteric bacteria in Hammersmith Hospital also carried mercury resistance (Schottel *et al.*, 1974). DNA sequence analyses has shown that the Tn21-type transposons carry both a copy of the *mer*

locus and an integron (see above) (Stokes and Hall, 1989; Grinsted *et al.*, 1990). Summers and co-workers (1993) have observed that resistance to mercury occurs frequently in human fecal flora and is correlated with the occurrence of multiple antibiotic resistance. How does this phenomenon become a public health concern? In the same report Summers' group found that the mercury released from the amalgam in "silver" dental fillings in monkeys led to the rapid enrichment of many different mercury-resistant bacteria in the oral and fecal flora. They suggest that in humans this chronic and biologically significant exposure to mercury may foster the persistence of multidrug-resistant microbes through selection of linked markers.

B. Other examples

There may well be other examples of this phenomenon, where subclinical concentrations of an antibiotic could serve as selection for the maintenance (and propagation) of genetic elements and their resident resistance genes. There is also maintenance by constant selection pressure for other phenotypes, a type of "linked" selection (we have mentioned the role of mercury in this respect). How else does one explain the fact that streptomycin and chloramphenicol resistance can be still found on plasmids in hospitals, even though these antibiotics are no longer used? Are there other positive selective functions carried by plasmids? Resistance to ultraviolet light or other physical or chemical toxins (e.g. detergents, disinfectants) would be a possibility. Is it also conceivable that plasmids improve the fitness of their hosts under "normal" conditions? Evidence for this comes from the work of Lenski (personal communication, 1996).

VII. CONCLUDING REMARKS—FOR NOW AND THE FUTURE

It should be apparent from the foregoing discussion of antibiotic modification that there must be a substantial pool of antibiotic resistance genes (or close relatives of these genes) in nature. Gene flux between bacterial replicons and their hosts is likely to be the rule rather than the exception, and it appears to respond quickly to environmental changes (Levy and Novick, 1986; Levy and Miller, 1989; Hughes and Datta, 1983). This gene pool is readily accessible to bacteria when they are exposed to the strong selective pressure of antibiotic usage—in hospitals, for veterinary and agricultural purposes, and as growth promoters in animal and poultry husbandry. It is a life-or-death situation for microbes, and they have survived. A better knowledge

of the components of this gene pool, particularly with respect to what might happen on the introduction of a new chemical entity such as an antimicrobial agent, might, on the one hand, permit early warning and subsequent chemical modification of antibiotics to permit them to elude potential resistance mechanisms and, on the other, lead to more prudent use of antibiotics under circumstances where the presence of specific resistance determinants can be predicted.

The development of resistance to antimicrobial agents is inevitable, in response to the strong selective pressure and extensive use of antibiotics. Resistance may develop as the result of mutation or acquisition, or a combination of the two. The use of antibiotics should be such as to delay the inevitable, and knowledge gained over the past 50 years if correctly interpreted and used to modify current practices appropriately should permit this. Unfortunately, for all of the antimicrobial agents in current use, we have reached a state of no return. The American Society for Microbiology Task Force on Antibiotic Resistance has made a number of recommendations to deal with the current crisis of antibiotic resistant microbes (see Table 3.8; ASM,

TABLE 3.8 Recommendations from the American Society for Microbiology Task Force on Antibiotic Resistance

Establish a national surveillance system immediately.
Lead agency should be the National Center for Infectious Diseases of the U.S. Centers for Disease Control (CDC) and should involve the National Institute of Allergy and Infectious Disease of the National Institutes of Health (NIH), the Environmental Protection Agency, and the Food and Drug Administration.
Strengthen professional and public education in the area of infectious disease and antibiotics to reduce inappropriate usage of antibiotics.
The curriculum for health professionals should include the appropriate handling, diagnosis, and treatment of infectious disease and antibiotic resistance.
Reduce the spread of infectious agents and antibiotic resistance in hospitals, nursing homes, day care facilities, and food production industries.
Educate patients and food producers.
Improve antimicrobial use for cost-effective treatment and preservation of effectiveness.
Increase basic research directed toward development of new antimicrobial compounds, effective vaccines, and other prevention measures.
Fund areas directly related to new and emerging infections and antibiotic resistance.
Fund basic research in bacterial genetics and metabolic pathways.
Establish a culture collection containing representative antibiotic-resistance biotypes of pathogens.
Sequence genomes of microbial pathogens.
Develop better diagnostic techniques.
Develop vaccines and other preventative measures.

1995). It has been suggested that such measures can, at the least, maintain and improve the status quo.

Two of the options that would permit continued success of antibiotic therapy in the face of increasing resistance are: (a) the discovery of new antibiotics (by "new" this implies novel chemical structures) and (b) the development of agents, that might be used in combination with existing antibiotics, to interfere with the biochemical resistance mechanisms. Such a strategy has already been partially successful in the development of inhibitors of β -lactamases to permit "old" antibiotics to be used. However, there appears to be little success (or effort) in applying this approach to other antibiotic classes. In our discussion of biochemical mechanisms (Section II) we have noted a number of cases where this approach could be taken (e.g. fluorinated analogs of chloramphenicol). With respect to novel antibiotics, several valid approaches exist: (a) natural product screening, especially directed at products of the 99.9% of microbes that cannot be grown in the laboratory; (b) combinatorial chemistry that can be used as a means of discovery of new active molecules or to new substitutions on known ring structures; and (c) rational chemical design based on identification of specific biochemical targets. The success of these methods will depend on the availability of cell-based and biochemical assays that will detect low concentrations of active molecules by high flux screening methods. It seems redundant to insist on the requirement for early identification of natural resistance mechanisms for any compounds of interest (thus permitting the design of analogs) and the study of structure-toxicity relationships at the earliest stage possible.

Last, but not least, the introduction of a novel antimicrobial agent into clinical practice must be accompanied by strict limitations on its use. No novel therapeutic should be used for other than human use under prescription, and no structural analog should be employed for "other" purposes.

Antifungal agents

Ana Espinel-Ingroff

Medical College of Virginia Commonwealth University

GLOSSARY

emerging fungal infections Fungal infections caused by new or uncommon fungi.

granulocytopenia/neutropenia Acquired or chemically induced immunosuppression caused by low white blood cell counts.

immunocompromised Having a defect in the immune system.

in vitro and in vivo Describing or referring to studies carried out in the test tube and in animals, respectively.

mycoses and mycotic infections Diseases caused by yeasts or molds.

nephrotoxicity Damage to the kidney cells.

opportunistic infections Infections caused by saprophytic fungi or not true parasites.

Antifungal Agents are naturally occurring or synthetically produced compounds that have *in vitro* or *in vivo* activity against yeasts, molds, or each. Fungi and mammalian cells are eukaryotes, and antifungal agents that inhibit synthesis of proteins, RNA, and DNA are potentially toxic to mammalian cells.

Fungi can be unicellular (yeasts) and multicellular or filamentous (molds) microorganisms. Some medically important fungi can exist in both of these morphologic forms and are called dimorphic fungi. Of the estimated 250 000 fungal species described, fewer than 150 are known to be etiologic agents of disease in

humans. Most fungi associated with disease are considered opportunistic pathogens (especially the yeasts) because they live as normal flora in humans, lower animals, and plants and rarely cause disease in otherwise healthy individuals. Many fungi, on the other hand, are important plant and lower animal parasites and can cause damage to crops (wheat rust, corn smut, etc.) and to fruit (banana wilt), forest (Dutch elm disease), and ornamental trees and other plants. Historically, the potato famine, which was the reason for the great migration from Ireland to the Americas, was caused by a fungal infection (potato blight). At the same time, fungi and their products play an important economic role in the production of alcohol, certain acids, steroids, antibiotics, etc.

Due to the high incidence of toxicity among antifungal agents and the perception before the 1970s that the number of severe and invasive infections was low, only 12 antifungal agents are currently licensed for the treatment of systemic fungal infections: the polyene amphotericin B and its three lipid formulations, the pyrimidine synthesis inhibitor 5-fluorocytosine (flucytosine), the imidazoles miconazole and ketoconazole, the triazoles fluconazole, itraconazole and voriconazole, and the echinocandin caspofungin. However, the number of fungal diseases caused by both yeasts and molds has significantly increased during the past 20 years, especially among the increased number of immunocompromised patients, who are at high risk for life-threatening mycoses.

TABLE 4.1 (Continued)

Benzimidazoles and methylbenz-imidazole carbamates	Nuclear division	Carbendazim Benomyl	Agriculture
Morpholines	Ergosterol biosynthesis inhibition	Thiophanate Amorolfine	Topical
		Fenpropimorph Tridemorph	Agriculture
Pyridines		Buthiobate	Agriculture
Echinocandins	Fungal $\beta(1,3)$ -glucan synthesis inhibition	Pyrifenoxy Papulocandins	None
		Caspofungin	Treatment of candidemia and refractory aspergillosis
Pradimicins	Fungal saccharide (mannoproteins)	Anidulafungin Pradamicin FA-2 (BMY 28864)	Under investigation Under investigation
Benanomycins		Benanomycin A	Under investigation
Polyoxins	Fungal chitin synthase inhibition	Polyoxin D	None
Nikkomycins		Nikkomycin Z	Under investigation
Sordarins	Protein synthesis inhibition	GM 222712 GM 237354 GM 211676 GM 193663	Under investigation
Cinnamic acid	Cell wall	Dimethomorph	Agriculture
Oomycete fungicide	Oxidative phosphorylation	Fluazynam	Agriculture
Phthalimides	Non-specific	Captan Captafol Folpet	Agriculture
Cationic peptides	Lipid bilayer of biological membranes	Natural peptides Cecropin Indolicidin	Under investigation
		Synthetic peptides	Under investigation
Amino acid analogs	Amino acid synthesis interference	RI 331 Azoxybacillins Cispentacin	Under investigation

^aOnly licensed, commonly used, and antifungals under clinical investigation are listed; see text for other antifungals.

^bClinical and veterinary use; other applications for use in humans only.

^cA human product used in veterinary practice.

agents currently licensed for clinical, veterinary, or agricultural uses. A shorter description is provided for antifungal compounds that are in the last phases of clinical development, under clinical trials in humans, or that have been discontinued from additional clinical evaluation. The former compounds have potential use as therapeutic agents. More detailed data regarding these agents are found in the references.

I. THE POLYENES

The polyenes are macrolide molecules that target membranes containing ergosterol, which is an important

sterol in the fungal cell membranes. Traces of ergosterol are also involved in the overall cell cycle of fungi.

A. Amphotericin B

Amphotericin B is the most important of the 200 polyenes. Amphotericin B replaced 2-hydroxystilbamidine in the treatment of blastomycosis in the mid-1960s. Two amphotericins (A and B) were isolated in the 1950s from *Streptomyces nodosus*, an aerobic bacterium, from a soil sample from Venezuela's Orinoco River Valley. Amphotericin B (the most active molecule) has seven conjugated double bonds, an internal ester, a free carboxyl group, and a glycoside side-chain with a primary amino group (Fig. 4.1A). It is unstable to

FIGURE 4.1 Chemical structures of some systemic licensed antifungal agents: (A) amphotericin B, (B) 5-fluorocytosine, (C) miconazole, (D) ketoconazole, (E) fluconazole, and (F) itraconazole.

heat, light, and acid pH. The fungistatic (inhibition of fungal growth) and fungicidal (lethal) activity of amphotericin B is due to its ability to combine with ergosterol in the cell membranes of susceptible fungi. Pores or channels are formed causing osmotic instability and loss of membrane integrity. This effect is not specific; it extends to mammalian cells. The drug binds to cholesterol, creating the high toxicity associated with all conventional polyene agents. A second mechanism of antifungal action has been proposed for amphotericin B, which is oxidation dependent. Amphotericin B is highly protein bound (91–95%). Peak serum of 1–3 µg/ml and trough concentrations of 0.5–1.1 µg/ml are usually measured after the intravenous (i.v.) administration of 0.6 mg/kg doses. Its half-life of elimination is 24–48 µh, with a long terminal half-life of up to 15 days.

Although resistance to amphotericin B is rare, quantitative and qualitative changes in the cell membrane sterols have been associated with the development of microbiological resistance both *in vitro* and *in vivo*. Clinically, resistance to amphotericin B has become an important problem, particularly with certain yeast and mold species, such as *Candida lusitanae*, *C. krusei*, *C. glabrata*, *Aspergillus terreus*, *Fusarium* spp., *Malassezia furfur*, *Pseudallescheria boydii*, *Scedosporium prolificans*, *Trichosporon beigelii*, and other emerging fungal pathogens.

The *in vitro* spectrum of activity of amphotericin B includes yeasts, dimorphic fungi, and most of the opportunistic filamentous fungi. Clinically, amphotericin B is considered the gold standard antifungal agent for the management of most systemic and disseminated fungal infections caused by both yeasts and molds, including endemic (infections caused by the dimorphic fungi, *Coccidioides immitis*, *Histoplasma capsulatum*, and *Blastomyces dermatitidis*) and opportunistic mycoses. Although it penetrates poorly into the cerebrospinal fluid (CSF), amphotericin B is effective in the treatment of both *Candida* and *Cryptococcus meningitis* alone and/or in combination with 5-fluorocytosine. Current recommendations regarding daily dosage, total dosage, duration, and its use in combination with other antifungal agents are based on the type of infection and the status of the host. Since severe fungal infections in the granulocytopenic host are difficult to diagnose and cause much mortality, empirical antifungal therapy with amphotericin B and other agents has improved patient care. Systemic prophylaxis for patients at high risk for invasive mycoses has also evolved. Toxicity is the limiting factor during amphotericin B therapy and has been classified as acute or delayed (Table 4.2). Nephrotoxicity is the most significant delayed adverse effect. Therefore, close monitoring of renal function tests,

TABLE 4.2 Adverse Side effects of the Licensed Systemic Antifungal Agents^a

Side effect	Drug
Fever, chills	A, K, C, V
Rash	FC, K, I, FL, C, V
Nausea, vomiting	A, FC, K, I, FL, V
Abdominal pain	FC, K, V
Anorexia	A, K
Diarrhea	FC, V
Elevation of transaminases	FC, K, I, FL, C, V
Hepatitis (rare)	FC, K, I, FL
Anemia	A, FC
Leukopenia, thrombocytopenia	FC
Decreased renal function (azotemia, acidosis, hypokalemia, etc.)	A, C
Decreased testosterone synthesis	K (I, rare)
Adrenal insufficiency, menstrual irregularities, female alopecia	K
Syndrome of mineralocorticoid excess, pedal edema	I
Headache	A, FC, K, I, FL, V
Photophobia	K, V
Dizziness	I, V
Seizures	FL
Confusion	FC, V
Arthralgia, myalgia, thrombophlebitis	A
Abnormal vision	V
Cardiovascular (tachycardia and others)	C, V
Hypokalemia	C, V

^aSee Groll *et al.* (1998) for more detailed information. A, amphotericin B; FC, flucytosine; K, ketoconazole; FL, fluconazole; I, itraconazole; C, caspofungin, and V, voriconazole. (% of side effects for C and V are usually lower than those for other licensed agents.)

bicarbonate, electrolytes including magnesium, diuresis, and hydration status is recommended during amphotericin B therapy. Adverse drug interactions can occur with the administration of electrolytes and other concomitant drugs. This drug is also used for the treatment of systemic infections in small animals, especially blastomycosis in dogs, but it is not effective against aspergillosis. Side effects (especially in cats) and drug interactions are similar to those in humans.

B. Nystatin

Nystatin was the first of the polyenes to be discovered when it was isolated from *S. noursei* in the early 1950s. It is an amphoteric tetrane macrolide that has a similar structure (Fig. 4.2A) and identical mechanism of action to those of conventional amphotericin B. Although it has an *in vitro* spectrum of activity similar to that of amphotericin B, this antifungal is used mostly for the therapy of gastrointestinal (orally) and mucocutaneous candidiasis (topically). This is not only due to its toxicity after parenteral administration to humans and lower animals but also to its lack of effectiveness when given i.v. to experimental animals.

FIGURE 4.2 Chemical structures of the most commonly used topical antifungal agents: (A) nystatin, (B) griseofulvin, (C) clotrimazole, and (D) terbinafine.

It is used for candidiasis in small animals and birds and for otitis caused by *Microsporum canis*.

C. Lipid formulations

1. Amphotericin B lipid formulations

In an attempt to decrease the toxicity and increase the efficacy of amphotericin B in patients with deep-seated fungal infections refractory to conventional therapy, several lipid formulations of this antifungal have been developed since the 1980s. These preparations have selective toxicity or affinity for fungal cell membranes and theoretically promote the delivery of the drug to the site of infection while avoiding the toxicity of supra-maximal doses of conventional amphotericin B. Because lysis of human erythrocytes is reduced, higher doses of amphotericin B can be safely used. Three lipid formulations of amphotericin B have been evaluated in

clinical trials: an amphotericin B lipid complex, an amphotericin B colloidal dispersion, and a liposomal amphotericin B. However, despite evidence of nephrotoxicity reduction, a significant improvement in their efficacy compared to conventional amphotericin B has not been clearly demonstrated. Although these three formulations have been approved for the treatment of invasive fungal infections that have failed conventional amphotericin B therapy, enough information is not available regarding their pharmacokinetics, drug interactions, long-term toxicities, and the differences in both efficacy and tolerance among the three formulations. Also, the most cost-effective clinical role of these agents as first-line therapies has not been elucidated.

a. Liposomal amphotericin B

In the only commercially available liposomal formulation (ambisome), amphotericin B is incorporated

into small unilamellar, spherical vesicles (60–70-nm liposomes). These liposomes contain hydrogenated soy phosphatidylcholine and distearyl phosphatidylglycerol stabilized by cholesterol and amphotericin B in a 2:0.8:1:0.4 molar ratio. In the first liposomes, amphotericin B was incorporated into large, multilamellar liposomes that contained two phospholipids, dimyristoyl phosphatidylcholine (DMPC) and dimyristoyl phosphatidylglycerol (DMPG), in a 7:3 molar ratio (5–10% mole ratio of amphotericin B to lipid). This formulation is not commercially available, but it led to the development of commercial formulations.

b. Amphotericin B lipid complex

Amphotericin B lipid complex (abelcet) contains a DMPC/DMPG lipid formulation in a 7:3 ratio and a 50% molar ratio of amphotericin B to lipid complexes that form ribbon-like structures.

c. Amphotericin B colloidal dispersion

Amphotericin B colloidal dispersion (amphotec) contains cholesteryl sulfate and amphotericin B in a 1:1 molar ratio. This formulation is a stable complex of disk-like structures (122-nm in diameter and 4-nm thickness).

2. Liposomal nystatin

In order to protect human erythrocytes from nystatin toxicity and thus make this drug available as a systemic therapeutic agent, nystatin has been incorporated into stable, multilamellar liposomes, which contain DMPC and DMPG in a 7:3 ratio. It has been demonstrated that the efficacy of liposomal nystatin is significantly superior to that of conventional nystatin and is well tolerated in experimental murine models of systemic candidiasis and aspergillosis (fungal infections caused by *Candida* spp. and *Aspergillus* spp.). In patients with hematological malignancies and refractory febrile neutropenia, dose-limiting nephrotoxicity has not been observed at high dosages. A 37% response to therapy has been documented in a small group of patients. Ongoing clinical trials would confirm the potential value of liposomal nystatin.

D. Candicidin

Candicidin is a conjugated heptaene complex produced by *S. griseus* that is selectively and highly active *in vitro* against yeasts. It is more toxic for mammalian cells than either amphotericin B or nystatin; therefore,

its use was restricted to topical applications for the treatment of vaginal candidiasis (infections by *Candida albicans* and other *Candida* spp.).

E. Pimaricin

Pimaricin is a tetraene polyene produced by *S. natalensis*. It has a higher binding specificity for cholesterol than for ergosterol and, therefore, it is highly toxic for mammalian cells. The therapeutic use of pimaricin is limited to the topical treatment of keratitis (eye infections; also in horses) caused by the molds, *Fusarium* spp., *Acremonium* spp., and other species.

II. GRISEOFULVIN

Griseofulvin is a phenolic, benzyfuran cyclohexane agent (Fig. 4.2B) that binds to RNA. It is a product of *Penicillium janczewskii* and was the first antifungal agent to be developed as a systemic plant protectant. It acts as a potent inhibitor of thymidylate synthetase and interferes with the synthesis of DNA. It also inhibits microtubule formation and the synthesis of apical hyphal cell wall material. With the advent of terbinafine and itraconazole, the clinical use of griseofulvin as an oral agent for treatment of dermatophytic infections has become limited. However, it is frequently used for these infections in small animals, horses, and calves (skin only) as well as for equine sporotrichosis. Abdominal adverse side effects have been noted, especially in cats.

III. CYCLOHEXIMIDE

This is a glutaramide agent produced by *S. griseus*. This agent was among the three antifungals that were reported between 1944 and 1947. Although cycloheximide had clinical use in the past, it is currently used as a plant fungicide and in the preparation of laboratory media.

IV. PYRROLNITRIN, FENPICLONIL, AND FLUDIOXONIL

Pyrrolnitrin is the fermentation product of *Pseudomonas* spp. It was used in the past as a topical agent.

Fenpiclonil and fludioxonil (related to pyrrolnitrin) were the first of the phenylpyrrols to be introduced as cereal seed fungicides.

V. THE SYNTHETIC PYRIMIDINES

A. 5-Fluorocytosine (5-FC, flucytosine)

The synthetic 5-fluorocytosine is an antifungal metabolite that was first developed as an antitumor agent, but it is not effective against tumors. It is an oral, low-molecular-weight, fluorinated pyrimidine related to 5-fluorouracil and floxuridine (Fig. 4.1B). It acts as a competitive antimetabolite for uracil in the synthesis of yeast RNA; it also interferes with thymidylate synthetase. Several enzymes are involved in the mode of action of 5-fluorocytosine. The first step is initiated by the uptake of the drug by a cell membrane-bound permease. Inside the cell, the drug is deaminated to 5-fluorouracil, which is the main active form of the drug. These activities can be antagonized *in vitro* by a variety of purines and pyrimidine bases and nucleosides. At least two metabolic sites are responsible for resistance to this compound: one involves the enzyme cytosine permease, which is responsible for the uptake of the drug into the fungal cell, and the other involves the enzyme cytosine deaminase, which is responsible for the deamination of the drug to 5-fluorouracil. Alterations of the genetic

1. 1-Chlorobenzyl-2-methylbenzimidazole

The azole 1-chlorobenzyl-2-methylbenzimidazole was developed specifically as an anti-*Candida* agent. It has been used in the past in the treatment of superficial yeast and dermatophytic infections.

2. Thiabendazole

Thiabendazole was developed as an anthelmintic agent and has a limited activity against dermatophytes. It was also used in the past in the treatment of superficial yeast and dermatophytic infections. Thiabendazole has been used for aspergillosis and penicillosis in dogs.

B. N-substituted (mono) imidazoles

In this group, the imidazole ring is intact and substitutions are made at one of the two nitrogen molecules. At least three series of such compounds have emerged for clinical and agricultural use. In the triphenylmethane series, substitutions are made at the nonsymmetrical carbon atom attached to one nitrogen molecule of the imidazole ring. In the second series, the substitutions are made at a phenethyl configuration attached to the nitrogen molecule. The dioxolane series is based on a 1,3-dioxolane molecule rather than on the 1-phenethyl molecule. These series vary in spectrum, specific level of antifungal activity, routes of administration, and potential uses.

1. Clotrimazole

Clotrimazole is the first member of the triphenylmethane series of clinical importance (Fig. 4.2C). It has good *in vitro* activity at very low concentrations against a large variety of fungi (yeasts and molds). However, hepatic enzymatic inactivation of this compound, after systemic administration, has limited its use to topical applications (1% cream, lotion, solution, tincture, and vaginal cream) for superficial mycoses (nail, scalp, and skin infections) caused by the dermatophytes and *M. furfur*, for initial and/or mild oropharyngeal candidiasis (OPC; 10-mg oral troche), and for the intravaginal therapy (single application of 500-mg intravaginal tablet) of vulvovaginal candidiasis. Other intravaginal drugs require 3–7-day applications. This drug is also used for candidal stomatitis, dermatophytic infections, and nasal aspergillosis (infused through tubes) in dogs.

2. Bifonazole

Bifonazole is a halogen-free biphenylphenyl methane derivative. Bifonazole is seldom utilized as a topical

agent for superficial infections, despite its broad spectrum of activity. Its limited use is the result of its toxic side effects for mammalian cells. Bifonazole is retained in the dermis for a longer time than clotrimazole.

3. Econazole, isoconazole, oxiconazole, and tioconazole

Other frequently used topical imidazoles include econazole (1% cream), isoconazole (1% cream), oxiconazole (1% cream and lotion), and tioconazole (6.5% vaginal ointment) (Table 4.1). As with clotrimazole, a single application of tioconazole is effective in the management of vulvovaginal candidiasis and as a nail lacquer for fungal onychomycosis (nail infections). Mild to moderate vulvovaginal burning has been associated with intravaginal therapy. Oxiconazole and econazole are less effective than terbinafine and itraconazole in the treatment of onychomycosis and other infections caused by the dermatophytes. Although topical agents do not cure onychomycosis as oral drugs do, they may slow down the spread of this infection. However, the recommended drugs for the treatment of onychomycosis are terbinafine (by dermatophytes) and itraconazole.

4. Lanconazole

In recent years, lanconazole has been introduced for topical treatment of dermatomycoses. It appears to have superior activity *in vitro* and in experimental infections in guinea pigs than those of earlier compound.

5. Miconazole

Miconazole was the first azole derivative to be administered intravenously for the therapy of systemic fungal infections. Its use is limited, due to toxicity and high relapse rates, to certain cases of invasive infections caused by the opportunistic mold, *P. boydii*. Since this compound is insoluble in water, it was dissolved in a polyethoxylated castor oil for its systemic administration. This solvent appears to be the cause of the majority of miconazole side effects (pruritus, headache, phlebitis, and hepatitis). On the other hand, miconazole is used for dermatophytic infections in large animals, fungal keratitis and pneumonia in horses, resistant yeast infections to nystatin in birds, and aspergillosis in raptors. However, safety and efficacy data are not available (veterinary use).

6. Ketoconazole

Ketoconazole was the first representative of the dioxolane series (Fig. 4.1D) to be introduced into clinical

TABLE 4.3 Adverse interactions of the licensed systemic azoles with other drugs during concomitant therapy^a

Azole	Concomitant drug	Adverse side effect of interaction
K, Fl, I	Nonsedating antihistamines, cisapride, terfenadine, astemizole	Fetal arrhythmia
K, Fl, I, V	Rifampin, isoniazid, phenobarbital, rifabutin, carbamazepine, and phenytoin	Reduce azole plasma concentrations
K, Fl, I, V	Phenytoin, benzodiazepines, rifampin	Induces the potential toxicity levels of cocompounds
K, I	Antacids, H ₂ antagonists, omeprazole, sucralfate, didanosine	Reduces azole absorption
K, Fl, I	Lovastatin, simvastatin	Rhabdomyolysis
I	Indinavir, vincristine, quinidine, digoxin, cyclosporine, tacrolimus, methylprednisolone, and ritonavir	Induces potential toxicity cocompounds
Fl, I, V	Warfarin, rifabutin, sulfonyleurea	Induces potential toxicity of cocompounds
K	Saquinavir, chlordiazepoxide, methylprednisone	Induces potential toxicity of these compounds
K	Protein-binding drugs	Increases the release of fractions of free drug
K, C, V	Cyclosporine A	Nephrotoxicity (concomitant use with C is not recommended)
C	Tacrolimus	Tacrolimus concentration can be decreased
C	Efavirenz, nevirapine, phenytoin, dexamethasone, carbamazepine, and rifampin	Can significantly reduce C concentrations (use of daily dose of 70 mg of C should be considered when C is co-administered with some of these compounds).

^aSee Groll *et al.* (1998) for more detailed information. K, ketoconazole; Fl, fluconazole; I, itraconazole; C, caspofungin; V, voriconazole.

use and was the first orally active azole. Ketoconazole requires a normal intragastric pH for absorption. Its bioavailability is highly dependent on the pH of the gastric contents; an increase in pH will decrease its absorption, for example, in patients with gastric achlorhydria or treated with antacids or H₂-receptor antagonists (Table 4.3). This drug should be taken with either orange juice or a carbonated beverage.

Ketoconazole pharmacokinetics corresponds to a dual model with an initial half-life of 1–4 h and a terminal half-life of 6–10 h, depending on the dose. This drug highly binds to plasma proteins and penetrates poorly into the CSF, urine, and saliva. Peak plasma concentrations of approximately 2, 8, and 20 µg/ml are measured 1–4 h after corresponding oral doses of 200, 400, and 800 mg. The most common and dose-dependent adverse effects of ketoconazole are nausea, anorexia, and vomiting (Table 4.2). They occur in 10% of the patients receiving a 400-mg dose and in approximately 50% of the patients taking 800-mg or higher doses. Another limiting factor of ketoconazole therapy is its numerous and significant adverse interactions with other concomitant drugs (see Table 4.3 for a summary of the interactions of the azoles with other drugs administered to patients during azole therapy).

In vitro, ketoconazole has a broad spectrum of activity comparable to that of miconazole and the triazoles. However, due to its adverse side effects, its adverse interaction with other drugs, and the high rate of relapses, ketoconazole has been replaced by itraconazole as an alternative to amphotericin B for the treatment of immunocompetent individuals with non-life-threatening, non-central nervous system, localized or disseminated histoplasmosis, blastomycosis, mucocutaneous

candidiasis, paracoccidioidomycosis, and selected forms of coccidioidomycosis. In non-cancer patients, this drug can be effective in the treatment of superficial *Candida* and dermatophytic infections when the latter are refractory to griseofulvin therapy. Therapeutic failure with ketoconazole has been associated with low serum levels; monitoring of these levels is recommended in such failures. Ketoconazole also has been used for a variety of systemic and superficial fungal infections in cats and dogs.

7. *Enilconazole*

This is the azole most widely used in veterinary practice for the intranasal treatment of aspergillosis and penicillosis as well as for dermatophytic infections. The side effects are few.

8. *Epoxiconazole, fluquinconazole, triticonazole, and prochloraz*

Epoxiconazole, fluquinconazole, and triticonazole are important agricultural fungicides which have a wider spectrum of activity than that of the earlier triazoles, triadimefon and propiconazole, and the imidazole, prochloraz, as systemic cereal fungicides. However, development of resistance to these compounds has been documented.

C. The triazoles

The triazoles are characterized by a more specific binding to fungal cell cytochromes than to mammalian cells due to the substitution of the imidazole ring by the triazole ring. Other beneficial effects of this substitution

are: (i) an improved resistance to metabolic degradation; (ii) an increased potency; and (iii) a superior antifungal activity. Although fluconazole, itraconazole and voriconazole are the only three triazoles currently licensed for antifungal systemic therapy, several other triazoles are at different levels of clinical evaluation. Voriconazole has been licensed in Europe (Table 4.1).

1. Fluconazole

Fluconazole is a relatively small molecule (Fig. 4.1E) that is partially water soluble, minimally protein bound, and excreted largely as an active drug in the urine. It penetrates well into the CSF and parenchyma of the brain and the eye, and it has a prolonged half-life (up to 25 h in humans). The pharmacokinetics are independent of the route of administration and of the drug formulation and are linear. Fluconazole is well absorbed orally (its total bioavailability exceeds 90%), and its absorption is not affected by food or gastric pH. Plasma concentrations of 2–7 µg/ml are usually measured in healthy subjects after corresponding single doses of 100 and 400 mg. After multiple doses, the peak plasma levels are 2.5 times higher than those of single doses. The CSF to serum fluconazole concentrations are between 0.5 and 0.9% in both healthy human subjects and laboratory animals.

Fluconazole does not have *in vitro* or *in vivo* activity against most molds. Both oral and i.v. formulations of fluconazole are available for the treatment of candidemia in nonneutropenic and other nonimmunosuppressed patients, mucosal candidiasis (oral, vaginal, and esophageal), and chronic mucocutaneous candidiasis in patients of all ages. Fluconazole is the current drug of choice for maintenance therapy of AIDS-associated cryptococcal and coccidioidal meningitis. It is also effective as prophylactic therapy for immunocompromised patients to prevent both superficial and life-threatening fungal infections. However, since the cost of fluconazole is high and resistance to this drug can develop during therapy, fluconazole prophylaxis should be reserved for HIV-infected individuals or AIDS patients, who are refractory and intolerant to topical agents, or for patients with prolonged (+2 weeks) and profound neutropenia (+1500 cells). Although the recommended dosage of fluconazole for adults is 100–400 mg qd, higher doses (+800 mg qd) are required for the treatment of severe invasive infections and for infections caused by a *Candida* spp. that exhibit a minimum inhibitory concentration (MIC) of +8 µg/ml. However, despite the fluconazole MIC obtained when the infecting yeast is either *Candida krusei* or *C. glabrata*, intrinsic resistance to these yeasts precludes its use for the treatment of such infections. In contrast to the imidazoles

and itraconazole, fluconazole does not exhibit major toxicity side effects (2.8–16%). However, when the dosage is increased above 1200 mg, adverse side effects are more frequent (Table 4.2). Fluconazole interactions with other concomitant drugs are similar to those reported with other azoles, but they are less frequent than those exhibited by ketoconazole and itraconazole (Table 4.3). Fluconazole has been used to treat nasal aspergillosis and penicillosis in small animals and birds when topical enilconazole is not feasible.

2. Itraconazole

Itraconazole is another commercially available oral triazole for the treatment of certain systemic mycoses. In contrast to fluconazole, itraconazole is insoluble in aqueous fluids; it penetrates poorly into the CSF and urine but well into skin and soft tissues; and it is highly protein bound (+90%). Its structure is closely related to that of ketoconazole (Fig. 4.1F), but itraconazole has a broader spectrum of *in vitro* and *in vivo* antifungal activity than those of both ketoconazole and fluconazole. Similar to ketoconazole, itraconazole is soluble only at low pH and is better absorbed when the patient is not fasting. Absorption is erratic in cancer patients or when the patient is taking concomitant H₂-receptor antagonists, omeprazole, or antacids. Therefore, this drug should be taken with food and/or acidic fluids. Plasma peak (1.5–4 h) and trough concentrations between 1 and 2.2 and 0.4 and 1.8 µg/ml, respectively, are usually obtained after 200-mg dosages (capsule) as either single daily dosages (po or bid) or after i.v. administration (bid) for 2 days and qd for more days; these concentrations are also obtained in cancer patients receiving 5 mg/kg divided into two oral solution dosages.

Clinically, itraconazole (200–400 mg/day) has supplanted ketoconazole as first-line therapy for endemic, non-life-threatening mycoses caused by *B. dermatitidis*, *C. immitis*, and *H. capsulatum* as well as by *Sporothrix schenckii*. For more severe mycoses, higher doses are recommended and clinical resistance may emerge. It can also be effective as a second-line agent for refractory or intolerant infections to conventional amphotericin B therapy, for example, infections by the phaeoid (dematiaceous or black molds or yeasts) fungi and *Aspergillus* spp. Itraconazole is commercially available as oral solution, tablet, and i.v. suspension. The oral solution is better absorbed than the tablet and has become useful for the treatment of HIV-associated oral and esophageal candidiasis, especially for those cases that are resistant to fluconazole. However, monitoring of itraconazole plasma concentrations is recommended during treatment of both superficial and invasive diseases: Drug concentration

+0.5 $\mu\text{g/ml}$ by high-performance liquid chromatography and +12 $\mu\text{g/ml}$ by bioassay appear to be critical for favorable clinical response. Treatment with itraconazole has been associated with less adverse and mostly transient side effects (+110%) than that with ketoconazole (Table 4.2), and these effects are usually observed when the patient takes up to 400 mg during several periods of time. Itraconazole has been used for the treatment of endemic mycoses, aspergillosis, and cryptococcosis in dogs (especially blastomycosis), equine sporotrichosis, and osteomyelitis caused by *C. immitis* in large animals, but its use is minimal.

No data are available regarding its side effects or drug interactions in animals.

3. Voriconazole (UK-109496)

Voriconazole is a novel fluconazole derivative obtained by replacement of one triazole moiety by fluoropyrimidine and α -methylation groups (Fig. 4.3A).

In contrast to fluconazole and similar to itraconazole, voriconazole is non-water soluble. As do the other azoles, voriconazole acts by inhibiting fungal cytochrome P450-dependent, 14- α -sterol

FIGURE 4.3 Chemical structures of three new triazoles: (A) voriconazole, (b) posaconazole, and (C) ravuconazole.

demethylase-mediated synthesis of ergosterol. Voriconazole pharmacokinetics in humans are non-linear. Following single oral doses, peak plasma concentrations were achieved after 2 h and multiple doses resulted in a higher (eight times) accumulation. The mean half-life of elimination is about 6 h. Voriconazole binds to proteins (65%), is extensively metabolized in the liver, and is found in the urine (78–88%) practically unchanged after a single dose. Voriconazole has an improved *in vitro* fungistatic activity and an increased potency against most fungi compared to those of fluconazole. It is fungicidal against some fungi, especially *Aspergillus* spp. However, less *in vitro* activity has been demonstrated for the opportunistic molds *Fusarium* spp., *Rhizopus arrhizus*, *S. schenckii*, and other less common emerging fungi. Studies in neutropenic animal models have demonstrated that voriconazole is superior to both amphotericin B and itraconazole for the treatment of certain opportunistic (especially aspergillosis) and endemic mycoses. This compound has undergone phase III evaluation for the treatment of invasive aspergillosis and infections refractory to established antifungal agents in humans. In the United States, voriconazole was approved May 24, 2002 for primary treatment of acute aspergillosis and as salvage therapy for serious fungal infections caused by *S. apiospermum* and *Fusarium* spp. However, the European label is for treatment of invasive aspergillosis, fluconazole-resistant serious invasive *Candida* infections (including *C. krusei*) and treatment of serious fungal infections caused by *Scedosporium* spp. and *Fusarium* spp. The drug has been well tolerated with only reversible side effects. In patients, hepatic (10–15%), transient visual (10–15%) and skin rash (1–5%) side effects have been observed.

4. Terconazole

Terconazole was the first triazole marketed for the topical treatment of vaginal candidiasis and superficial dermatophyte infections. Currently, it is only used for vulvovaginal candidiasis (0.4 and 0.8% vaginal creams and 80-mg vaginal suppositories).

D. Investigational triazoles

As fungal infections became an important health problem and resistance to established agents began to emerge, new triazoles were developed with a broader spectrum of antifungal activity. Early investigational triazoles, such as R 66905 (saperconazole), BAY R 8783, SCH 39304, and SCH 51048, were discontinued from further development due a variety of adverse

side effects. Two triazoles (posaconazole and ravuconazole) are currently under clinical investigation (Table 4.1) and others are at earlier stages of development.

1. SCH 39304, SCH 51048, and SCH 56592

a. SCH 39304

SCH 39304 is an N-substituted difluorophenyl triazole with both *in vitro* and *in vivo* (oral and parenteral) activity for both yeasts and molds. Although preliminary clinical trials demonstrated that this compound was well tolerated by humans and had good pharmacokinetic properties, additional clinical development was precluded by the incidence of hepatocellular carcinomas in laboratory animals during prolonged treatment.

b. SCH 51048

SCH 51048 is a tetrahydrofurane-based triazole that has superior potency (orally) than that of SCH 39304 toward the target enzyme and good *in vitro* activity against a variety of fungi. Although animal studies demonstrated that this drug is also orally effective for the treatment of systemic and superficial yeast and mold infections, the slow absorption rate from the intestinal track due to its poor water solubility precluded its further clinical development.

c. Posaconazole

Posaconazole (SCH 56592) is the product of a modification of the *n*-alkyl side chain of SCH 51048 which included a variety of chiral substituents (Fig. 4.3b). The *in vitro* fungistatic and fungicidal activities of posaconazole are similar to those of voriconazole and ravuconazole and superior or comparable to those of the established agents against yeasts, the dimorphic fungi, most opportunistic molds including *Aspergillus* spp., the Zygomycetes, certain phaeoid fungi, and the dermatophytes. It has been demonstrated that posaconazole is superior to itraconazole for the treatment of experimental invasive aspergillosis in animals infected with strains of *Aspergillus fumigatus* with high and low itraconazole MICs. Posaconazole has been effective in the treatment of patients with non-meningeal coccidioidomycosis, oropharyngeal infections and refractory and invasive mold infections including these caused by *Fusarium* spp. and the Zygomycetes. Similar results have been obtained for a variety of superficial and invasive infections in other animal models. The pharmacokinetics of

posaconazole have been studied in laboratory animals and although drug concentrations above both MIC and MFC (fungicidal) have been determined after a single po dose at 24 h, it has been demonstrated that plasma concentrations should be 5–10 times higher than the MIC. Also, its absorption from the intestinal tract is slow and peak serum concentrations are achieved 11–24 h after the actual dose. The clinical utility of this compound has yet to be determined in clinical trials in humans.

2. Ravuconazole (BMS-207147; ER-30346)

Ravuconazole (BMS-207147) is a novel oral thiazole-containing triazole (Fig. 4.3c) with a broad spectrum of activity against the majority of opportunistic pathogenic fungi. The antifungal activity of this triazole against *A. fumigatus* appears to be enhanced by the introduction of one carbon chain between the benzylic *tert* carbon and thiazole substituents and the cyano group on the aromatic ring attached to the thiazole. Ravuconazole has a similar or superior *in vitro* activity compared to those of the other investigational and established drugs against most pathogenic yeasts, with the exceptions of *C. tropicalis* and *C. glabrata*. Ravuconazole also has good *in vivo* antifungal activity in murine models for the treatment of invasive aspergillosis, candidiasis, and cryptococcosis. Ravuconazole shows good pharmacokinetics in animals that is similar to that of itraconazole. This indicates that ravuconazole is absorbed at levels comparable to those of itraconazole. However, the half-life of ravuconazole (4 h) is longer than that of itraconazole (1.4 h) and similar to that of fluconazole. The potential use of ravuconazole has yet to be determined in clinical trials in humans.

3. Saperconazole (R 66905)

Saperconazole is a lipophilic and poorly water-soluble fluorinated triazole; its chemical structure resembles that of itraconazole. Although both *in vitro* and *in vivo* antifungal activities were demonstrated against yeasts and molds and it was well tolerated during three clinical trials, this triazole was discontinued due to the incidence of malignant adrenal tumors in laboratory animals (long-term toxicity experiments).

4. BAY R 3783

This metabolite triazole was also discontinued from further clinical development due to the potential toxic effect during prolonged therapy.

5. SDZ 89-485

The antifungal activity of the D-enantiomer SDZ 89-485 antifungal triazole was demonstrated only in a few laboratory animal studies, and additional studies were not conducted with this compound.

6. D 0870

Although more *in vitro* and *in vivo* studies were conducted with D 0870 than with SDZ-89-485, and D 0870 showed good antifungal activity, this drug was also discontinued by its original developers. The *in vitro* activity of D 0870 is lower than that of itraconazole against *Aspergillus* spp., but higher for the common *Candida* spp. Therefore, evaluation of this compound has been continued by another pharmaceutical company for the treatment of OPC in HIV-infected individuals. It has also shown activity against the parasite *Trypanosoma cruzi*.

7. T-8581

T-8581 is a water-soluble 2-fluorobutanamide triazole derivative. High peak concentrations (7.14–12 µg/ml) of T-8581 were determined in the sera of laboratory animals following the administration of single oral doses of 10 mg/kg, and the drug was detected in the animals sera after 24 h. The half-life of T-8581 varies in the different animal models from 3.2 h in mice to 9.9 h in dogs. Animal studies suggest that the absorption of this compound is almost complete after po dosages. The maximum solubility of T-8581 is superior (41.8 mg/ml) to that of fluconazole (2.6 mg/ml), which suggests the potential use of this compound as an alternative to fluconazole for high-dose therapy.

T-8581 has shown potent *in vitro* antifungal activity against *Candida* spp., *C. neoformans*, and *A. fumigatus*. The activity of T-8581 is similar to that of fluconazole for the treatment of murine systemic candidiasis and superior to itraconazole for aspergillosis in rabbits. The safety of T-8581 is under evaluation.

8. UR-9746 and UR-9751

UR-9746 and UR-9751 are similar and recently introduced fluorinated triazoles that contain an *N*-morpholine ring, but UR-9746 has an extra hydroxyl group. The pharmacokinetics of these two compounds in laboratory animals has demonstrated peak concentrations (biological activity) of 184 (UR-9746) and 34 µg/ml (UR-9751) after 8 and 8–24 h, respectively. A slow decline of these levels was seen after 48 h. Chronic (19 days) doses of 100 mg/kg produced higher peak levels than single doses; two peaks were

observed after 1 and 8 h. However, the rate of decline of the drug after 24 h was faster after multiple than after single doses. Superior *in vitro* and *in vivo* activity than that of fluconazole has been demonstrated with these compounds against *Candida* spp., *C. neoformans*, *H. capsulatum*, and *C. immitis*. Both antifungals lacked detectable toxicity in experimental animal infections. Although UR-9751 MICs were fourfold higher than those of UR-9746, the *in vivo* activity in the animal model of systemic murine coccidioidomycosis was similar. Additional studies will determine the potential use of these compounds as systemic therapeutic agents in humans.

9. TAK 187 and SSY 726

Some *in vitro* and very little *in vivo* data are available for these new triazoles.

10. KP-103

KP-103 is another novel triazole that is being developed for the local treatment of dermatomycoses. Because this azole has low affinity for keratin, its antifungal activity is not lost as it penetrates skin tissue. The clinical values of this agent is to be determined in clinical trials.

VII. THE ALLYLAMINES

The allylamines are synthetic compounds that were introduced in the 1970s. They act by inhibiting squalene epoxidase, which results in a decrease of the ergosterol content and an accumulation of squalene affecting membrane structure and function (e.g. nutrient uptake).

A. Terbinafine

Terbinafine is the most active derivative of this class of antifungals. It has an excellent *in vitro* activity against the dermatophytes and other filamentous fungi, but its *in vitro* activity against the yeasts is controversial. It follows linear pharmacokinetics over a dose range of 125–750 mg; drug concentrations of 0.5–2.7 $\mu\text{g}/\text{ml}$ are detected 1 or 2 h after a single oral dose. Terbinafine has replaced griseofulvin and ketoconazole for the treatment of onychomycosis and other infections caused by dermatophytes (oral and topical). It is also effective for the treatment of vulvovaginal candidiasis. It is usually well tolerated at oral doses of 250 and 500 mg/day and the side effects (~10%) are gastrointestinal and cutaneous. The

metabolism of terbinafine may be decreased by cimetidine and increased by rifampin. Resistance has been reported for *Ustilago maydis*, a corn pathogen; resistance involved a decreased affinity for the target enzyme as well as a decreased accumulation of drug inside the fungal cell.

B. Naftifine

Pharmacokinetics and poor activity have limited the use of naftifine to topical treatment of dermatophytic infections.

VIII. THE BENZYLAMINES, THIOCARBAMATES, AND DITHIOCARBAMATES

The benzylamine, butenafine, and the thiocarbamates, tolnaftate, tolclate, and piritrade, also inhibit the synthesis of ergosterol at the level of squalene. Their clinical use is limited to the topical treatment of superficial dermatophytic infections.

The Bordeaux mixture (reaction product of copper sulfate and lime) was the only fungicide used until the discovery of the dithiocarbamate fungicides in the mid-1930s. Of those, mancozeb and thiram are widely used in agriculture, but because they are only surface-acting materials frequent spray applications are required. Ferbam, maneb, and zineb are not used as much.

THE BENZIMIDAZOLES AND METHYLBENZIMIDAZOLE CARBAMATES

A great impact on crop protection was evident with the introduction of the benzimidazoles and other systemic (penetrate the plant) fungicides. These compounds increased spray intervals to 14 days or more. The methylbenzimidazole carbamates (MBCs; carbendazim, benomyl, and thiophanate) inhibit nuclear division and are also systemic agricultural fungicides. However, since MBC-resistant strains of *B. cinerea* and *Penicillium expansum* have been isolated, these compounds should be used in combination with *N*-phenylcarbamate or agents that have a different mode of action.

THE MORPHOLINES

The morpholines interfere with $\delta 14$ reductase and $\delta 7$ and $\delta 8$ isomerase enzymes in the ergosterol

biosynthetic pathway, which leads to an increase of toxic sterols and an increase in the ergosterol content of the fungal cell.

A. Amorolfine

Amorolfine, a derivative of fenpropimorph, is the only morpholine that has a clinical application for the topical treatment of dermatophytic infections and candidal vaginitis.

B. Fenpropimorph, tridemorph, and other morpholines

Protein binding and side effects have precluded the clinical use of these morpholines, but they are important agricultural fungicides.

XI. THE PYRIDINES

The pyridines are another class of antifungal agents that inhibit lanosterol demethylase.

A. Buthiobate and pyrifenox

These agents are important agricultural fungicides.

XII. THE ECHINOCANDINS, PNEUMOCANDINS, AND PAPULOCANDINS

The echinocandins and papulocandins are naturally occurring metabolites of *Aspergillus nidulans* var. *echinulatus* (echinocandin B), *A. aculeatus* (aculeacin A), and *Papularia sphaerosperma* (papulocandin). They act specifically by inhibiting the synthesis of fungal $\beta(1,3)$ -glucan synthesis, which results in the depletion of glucan, an essential component of the fungal cell wall.

A. The papulocandins

The papulocandins A–D, L687781, BU4794F, and chaetiacandin have *in vitro* activity only against *Candida* spp., but poor *in vivo* activity, which precluded clinical development.

B. The echinocandins

The echinocandins include echinocandins, pneumocandins, aculeacins, mulundo- and deoxymulundocandin, sporiofungin, vWF 11899 A–C, and FR 901379.

The echinocandins have better *in vitro* and *in vivo* antifungal activity than the papulocandins. Pharmaceutical development has resulted in several semisynthetic echinocandins with an improved antifungal activity compared to those of the naturally occurring molecules described previously.

1. Cilofungin (LY 121019)

Cilofungin is a biosemisynthetic analog of the naturally occurring and toxic (erythrocytes lysis) 4-*n*-octyloxybenzoyl-echinocandin B. Although it showed good *in vitro* activity against *Candida* spp., this drug was discontinued due to the incidence of metabolic acidosis associated with its intravenous carrier, polyethylene glycol.

2. Anidulafungin (V-echinocandin, LY 303366)

This is another semisynthetic cyclic lipopeptide, which resulted from an increase of aromatic groups in the cilofungin side-chain (Fig. 4.4A). It has high potency and oral and parenteral bioavailability. In laboratory animals, peak levels in plasma (5 or 6 h) of 0.5–2.9 $\mu\text{g}/\text{ml}$ have been measured after single doses of 50–250 mg/kg. In humans, peak levels of 105–1624 ng/ml are measured after oral administrations of 100–1000 mg/kg; its pharmacokinetics is linear and the half-life is about 30 h and is dose independent. Tissue concentrations are usually higher than those in plasma in animals.

Anidulafungin has good *in vitro* activity against a variety of yeasts, including isolates resistant to itraconazole and fluconazole, and molds. This compound is not active against *C. neoformans*, *T. beigeli*, and *B. dermatitidis*; its MICs for certain molds are higher than those of the three new investigational azoles. However, its fungicidal activity against some species of *Candida* is superior to those of the azoles, which are mostly fungistatic drugs. Although the drug is well tolerated up to 700 mg/kg doses, gastrointestinal adverse effects have been observed with 100 mg/kg doses in human subjects. Potentially peak plasma concentrations in excess of MIC values have been demonstrated in rabbits and tissue levels are above MIC endpoints in major organs. In human volunteers, it exhibits linear pharmacokinetics after single oral doses of 100–1000 mg. Anidulafungin peak plasma levels occurred after 6–7 h after ingestion with an elimination half-life of approximately 30 h. Anidulafungin has *in vivo* activity in experimental murine (normal and immunocompromised animals) aspergillosis and candidiasis and *P. carinii* pneumonia. Clinical trials are being conducted to assess the efficacy of anidulafungin against *Candida* infections.

3. Anidulafungin derivatives

Several derivatives of anidulafungin have been synthesized including the phosphate derivative LY-307853 and phosphate ester derivatives LY-329960 and LY-333006, which had improved water solubility. Good activity has been demonstrated in a murine model of candidiasis with the two latter compounds.

Other echinocandin derivative is mulundocandin, which was obtained from a variant of *A. sydowii*. It has *in vitro* antifungal activity against itraconazole-resistant *Candida* spp. and *A. fumigatus*.

4. Cyclopeptamines

A-192411.29 is a novel cyclopeptamine antifungal lipopeptide derived by total synthesis from the structural template of the natural product echinocandin. It has similar *in vitro* activity to that of amphotericin B against *Candida* spp. and *C. neoformans* and partial activity against *A. fumigatus*.

5. Non-echinocandin macrocyclic lipopeptidolactones (FR-901469)

FR-901469 is a water-soluble, non-echinocandin-type lipoprotein fungal derivative. It has good *in vitro* activity against *C. albicans* and *A. fumigatus*.

C. Pneumocandin derivatives

The pneumocandins have similar structures to those of the echinocandins, but they possess a hexapeptide core with a β -hydroxyglutamine instead of the threonine residue, a branched-chain ^{14}C fatty acid acyl group at the N-terminal, and variable substituents at the C-terminal proline residue. The pneumocandins are fermentation products of the mold *Zalerion arboricola*.

Of the three naturally occurring pneumocandins (A–C), only A and B have certain antifungal activity *in vitro* and *in vivo* against *Candida* spp. and *Pneumocystis carinii* (in rodents), but they are non-water-soluble; this group has pneumocandin Ao (L-671329) and pneumocandin Bo (L-688786), which are fermentation products produced by *Zalerion arboricola* ATCC 20868 and related semisynthetic derivatives.

1. L-639989, L-733560, L-705589, and L-731373

Modification of the original pneumocandin B by phosphorylation of the free phenolic hydroxyl group led to the improved, water-soluble pneumocandin B phosphate (L-639989). Further modifications of pneumocandin B led to the water-soluble semisynthetic

molecules L-733560, L-705589, and L-731373. Although studies were conducted in laboratory animals, these molecules were not evaluated in humans.

D. Caspofungin (MK-0991 or L-743872)

Caspofungin acetate (Fig. 4.4B) is the product of a modification of L-733560 and was selected for further evaluation in clinical trials in humans. As are the other semisynthetic pneumocandins, caspofungin is water soluble. Caspofungin is highly protein bound (97%) with a half-life that ranges from 5 to 7.5 h and drug concentrations are usually higher in tissue than in plasma.

Caspofungin has fungistatic and fungicidal activities similar to those of anidulafungin against most *Candida* spp. and lower activity against the dimorphic fungi. It also has fungistatic *in vitro* activity against some of the other molds, especially *Aspergillus* spp. However, both anidulafungin and caspofungin pose difficulties regarding their *in vitro* laboratory evaluation and the data are controversial regarding their MICs for the molds. Animal studies have demonstrated that this compound has good *in vivo* activity not only against yeast infections but also in murine models of disseminated aspergillosis and pulmonary pneumocystosis and histoplasmosis. The drug is not effective for the treatment of disseminated experimental infections caused by *C. neoformans*. In laboratory animals, the drug is mostly well tolerated, but histamine release and mild hepatotoxicity have been reported. Caspofungin is generally well tolerated in humans, but side effects include hypokalemia, nephrotoxicity, chills, fever, intestinal, tachycardia, rash, and sweating (Table 4.2).

Data from 69 patients with either invasive refractory aspergillosis or intolerant infection to standard therapies demonstrated a 41% favorable response in patients receiving at least one dose of caspofungin and a 50% favorable response in patients receiving more than 7 days of therapy. Caspofungin has been licensed in the United States for candidemia and other *Candida* infections and for refractory aspergillosis.

E. Micafungin (FK 463)

FK 463 is a semisynthetic derivative of naturally occurring lipopeptide that was synthesized by a chemical modification from a product of the mould *Coleophoma empedri*. As the other related compounds, it has good *in vitro* activity against *Candida* and *Aspergillus* species, but it is inactive against *C. neoformans*, *T. beigeli*, and *F. solani*. It also has good activity

in vivo in experimental invasive candidiasis and pulmonary aspergillosis in neutropenic mice; the activity was similar to that of amphotericin B. The drug was well tolerated (up to 2.5–50 mg single, or 25 mg multiple doses, 7 days) in healthy adult male volunteers and adult bone marrow or peripheral stem cell transplant patients (200 mg/day, 10 days dosing average). The serum concentrations in the latter two groups of patients were higher than the serum levels obtained in experimental candidiasis and aspergillosis. Micafungin is protein binding (99%) and plasma concentrations attain a steady state by day 4 with repeated doses. Clearing of esophageal candidiasis symptoms has been demonstrated among 74 HIV-positive patients treated with micafungin at 50, 25, and 12.5 mg/day as 1-h infusion for a mean of 12 days. Diarrhea was the only side effect reported. Micafungin is undergoing Phase III clinical trials.

F. Other fungal cell inhibitors

Various aromatic natural products have been shown to have antifungal activity against *S. cerevisiae* (xanthofulvin) and *C. albicans* (Ro-41-0986 and its derivative Ro-09-3024).

XIII. THE PRADIMICINS AND BENANOMYCINS

The pradimicins and benanomycins are fungicidal metabolites (benzonaphthacene quinones) of *Actinomadura* spp., which were introduced in the 1980s. Several semisynthetic molecules have also been produced. They act by disrupting the cell membrane through a calcium-dependent binding with the saccharide component of mannoproteins, which results in disruption of the plasma membrane and leakage.

A. Pradimicin A (BMY 28567) and FA-2 (BMY 28864)

The poor solubility of pradimicin A led to the development of BMY 28864, which is a water-soluble derivative of pradimicin FA-2. BMY 28864 appears to have good *in vitro* and *in vivo* activity against most common yeasts and *A. fumigatus*. Clinical trials in humans have not been conducted.

B. BMS 181184

This compound is either a semisynthetic or biosynthetic derivative of BMY 28864. Although it was selected for further clinical evaluation due its promising *in vitro*

and *in vivo* data, elevation of liver transaminases in humans led to the discontinuation of this drug.

C. Benanomycin A

This compound has shown the best antifungal activity among the various benanomycins. Its great advantage compared to other new antifungals is its good *in vivo* activity in animals against *P. carinii*.

XIV. THE POLYOXINS AND NIKKOMYCINS

The polyoxins are produced by *S. cacaoi* and the nikkomycins by *S. tendae*. The former compounds were discovered during a search for new agricultural fungicides and pesticides. Both polyoxins and nikkomycins are pyrimidine nucleosides that inhibit the enzyme chitin synthase, which leads to the depletion of chitin in the fungal cell wall; they were introduced in the 1960s and 1970s. These molecules are transported into the cell via peptide permeases.

A. Polyoxin D

Although polyoxin D has *in vitro* antifungal activity against *C. immitis* (parasitic phase), *C. albicans*, and *C. neoformans*, it was not effective in the treatment of systemic candidiasis in mice.

B. Nikkomycin Z

This compound appears to have both *in vitro* and *in vivo* activity against *C. immitis*, *B. dermatitidis*, and *H. capsulatum*, which are highly chitinous fungi. It also has *in vitro* modest activity against *C. albicans* and *C. neoformans*. Studies to evaluate its safety have been conducted and clinical trials have been designed for the treatment of human coccidioidomycosis. These studies will determine its role as a therapeutic agent in humans.

XV. THE SORDARINS

The natural sordarin GR 135402 is an antifungal fermentation product of *Graphium putredinis*. The compounds GM 103663, GM 211676, GM 222712, and GM 237354 are synthetic derivatives of GR 135402. *In vitro*, GM 222712 and GM 237354 have shown broad-spectrum antifungal activity for a variety of yeasts and molds. Development of these two sordarines has been discontinued.

XVI. DIMETHOMORPH AND FLUAZINAM

Dimethomorph is a cinnamic acid derivative for use against *Plasmopara viticola* on vines and *Phytophthora infestans* on tomatoes and potatoes; it is not cross-resistant to phenylamides (systemic controllers of *Phycomycetes* plant infections). Fluazinam is used in vines and potatoes but also acts against *B. cinera* as an uncoupler of oxidative phosphorylation.

XVII. THE PHTHALIMIDES

The discovery of captan in 1952 and later of the related captafol and folpet initiated the proper protection of crops by the application of specific fungicides. Captan is also used to treat dermatophytic infections in horses and cattle, but it causes skin sensitization in horses.

XVIII. THE SPHINGOLIPID SYNTHESIS INHIBITORS

The sphingofungins, lipoxamycins, myriocin (ISP-1) and viridifungins selectively inhibit the fatty acid-like natural products. Fumonisin (produced by the corn and human pathogen *F. moniliforme*) and the structurally related *Alternaria* toxin are inhibitors of ceramide synthase; resemble the structurally unrelated australifungins. Because these compounds inhibit the mammalian sphingolipid pathway and cause accumulation of sphinganine (sphingolipid depletion of both mammalian and fungal cells), they are toxic. The fumonisins have been associated with cancer in humans and also could cause disease in animals.

Aureobasidin A is an inhibitor of the IPC (inositolphosphorylceramide) synthase that is produced by the black yeast *Aureobasidium pullulans*; it is the less toxic of this class of compounds. The oral fungicidal activity of aureobasidin has been demonstrated in experimental murine candidiasis. Khafrefungin and rustmicin (galbonolide A) also inhibit IPC synthase and have fungicidal activity against some yeasts and moulds by causing ceramide accumulation in the cell membrane. Due to their toxic effects, only aureobasidin A had both preclinical and Phase I clinical trials. However, its development was discontinued owing to its limited activity against *Candida* spp.

XIX. OTHER ANTIFUNGAL APPROACHES

A. Natural and synthetic cationic peptides

Cationic peptides provide a novel approach to antifungal therapy that warrants further investigation.

1. Cecropin

Cecropin is a natural lytic peptide that is not lethal to mammalian cells and binds to ergosterol. Its antifungal activity varies according to the fungal species being challenged.

2. Indolicidin

Indolicidin is a tridecapeptide that has good *in vitro* antifungal activity and when incorporated into liposomes has activity against experimental aspergillosis in animals.

3. Synthetic peptides

Synthetic peptides have been derived from the natural bactericidal-permeability increasing factor. They appear to have *in vitro* activity against *C. albicans*, *C. neoformans*, and *A. fumigatus* and also show synergistic activity with fluconazole *in vitro*.

B. Amino acid analogs

RI 331, the azoxybacillins, and cispentacin are amino acid analogs with good *in vitro* antifungal activity against *Aspergillus* spp. and the dermatophytes (RI 331 and azoxybacillins) and also good *in vivo* activity (cispentacin). RI 331 and the azoxybacillins inhibit homoserine dehydrogenase and the biosynthesis of sulfur-containing amino acids, respectively. The derivative of histatin 5 called P-113 has antifungal *in vitro* activity against *Candida* species.

Antisense RNAs

Andrea Denise Branch

The Mount Sinai School of Medicine

GLOSSARY

artificial RNAs RNA molecules expressed from genes that have been introduced into cells (transgenes) or RNA molecules synthesized in cell-free systems. The mode of action of artificial antisense RNAs is under active investigation. In some biological systems, artificial RNAs may themselves form double-stranded RNAs that mediate target-gene inhibition through novel mechanisms.

complementarity A measure of the percentage of nucleotides in two sequences that are theoretically able to form Watson–Crick base pairs.

cosuppression A type of posttranscriptional gene silencing in which transcripts of both an endogenous gene and an homologous transgene are synthesized and then degraded.

homology-dependent viral resistance A form of posttranscriptional gene silencing in which viral RNAs are degraded in transgenic plants expressing RNAs homologous to viral RNAs, resulting in inhibition of viral replication and attenuation of virus symptoms.

perfect double-stranded RNA (dsRNA) duplex A helical structure in which two segments from a single RNA molecule (an intramolecular duplex), or segments of two separate RNA molecules (an intermolecular duplex) in an anti-parallel orientation to each other form an uninterrupted series of Watson–Crick base pairs (C pairing with G; A pairing with U).

posttranscriptional gene silencing A process through which specific RNAs are degraded posttranscriptionally, resulting in loss of expression of associated genes.

RNA interference (RNAi) An efficient process that allows small (21–23 nucleotide-long) RNAs derived from double-stranded RNAs to inhibit (silence) specific target genes. The small interfering RNAs (siRNAs) that mediate RNAi may be produced through the cleavage of longer double-stranded RNAs, by an enzyme called Dicer, or they may be derived from artificial siRNA duplexes.

Antisense RNAs are RNA molecules that bind to a second, sense, RNA through complementary Watson–Crick base pairing of anti-parallel strands; RNA molecules that are at least 70% complementary to a second RNA for at least 30 nucleotides and thus have the potential for binding; or RNA molecules that are transcribed from the DNA strand opposite that of a second RNA. Antisense RNAs in gene therapy are complementary to target RNAs and are intended to eliminate the expression of specific genes; target RNAs may be either associated with diseases or with normal cellular functions. Naturally occurring antisense RNAs comprise a structurally and functionally diverse group that includes RNAs known to bind to their target RNAs and RNAs that simply contain sequences complementary to other previously identified RNAs.

In 1984, Izant and Weintraub thrust antisense RNA into the center stage of molecular research by proposing

that artificial antisense RNAs could be used to eliminate the expression of specific target genes, offering an alternative to the labors of classical mutational analysis. Rather than producing random mutations and then screening for those affecting genes of interest, they suggested that mutants could be created at will by introducing antisense RNAs complementary to sense transcripts of selected genes. They envisioned antisense RNAs binding to messenger RNAs (mRNAs) or their precursors, forming duplexes, and thereby inhibiting gene expression. The promise of streamlined genetic analysis, and improved pharmaceutical agents, livestock, and crops stimulated tremendous interest in antisense technology in members of the research community and on Wall Street. However, artificial antisense RNAs have not always performed as intended. The molecular events responsible for their unexpected behavior are not yet known, but enough information has emerged to indicate that these events merit thorough investigation. To understand the properties of artificial antisense RNA and to gain a more complete understanding of RNA's regulatory functions, it is essential to study both naturally occurring and artificial antisense RNA. This collection of molecules includes RNAs known to alter the expression of their sense RNA counterparts and RNAs whose sequences appear to equip them to interact with their sense counterparts (i.e., RNAs that are at least 70% complementary to a second RNA for at least 30 nucleotides). Many natural and artificial antisense RNAs exist—far too many for each to be discussed here. Therefore, this article focuses on the principles governing their behavior. (Information about antisense oligomers composed of DNA is not included, but has been reviewed by the author.)

I. INTRODUCTION

A. Naturally occurring antisense RNAs are extremely versatile

Antisense RNAs are best known for their ability to eliminate the expression of target RNAs by binding to complementary sequences. However, antisense RNAs do much more than turn off other genes. For example, in virus-infected mammalian cells, antisense RNA combines with sense RNA to form biologically active double-stranded RNA (dsRNA), which triggers the interferon (IFN) response. Other antisense RNAs are involved in RNA maturation. These molecules are often omitted from lists of antisense RNAs because they promote expression of their target RNAs, rather than inhibit it. However, there has never been a requirement

for antisense RNAs to function as negative regulators of gene expression. The antisense RNAs involved in RNA maturation illustrate how complementary RNA sequences contribute to essential cellular functions. The guide RNAs of certain parasites bind to mitochondrial mRNA precursors through short complementary regions and direct upstream editing of the pre-mRNA. (RNA editing is any process leading to an alteration in the coding capacity of an mRNA, other than splicing or 3'-end processing). Similarly, small nucleolar RNAs (snoRNAs) bind to complementary regions of ribosomal RNA (rRNA) precursors, leading to methylase-mediated site-specific modification of the precursor.

Of the antisense RNAs on the frontiers of research, those transcribed from mammalian genes are among the most intriguing and in greatest need of further investigation. Based on evidence showing that certain of these RNAs down-regulate their targets—diminishing synthesis of sense RNA, interfering with pre-mRNA processing, and inhibiting sense RNA translation—it has generally been assumed that any newly discovered antisense RNA would also function as a negative regulator. However, recent data indicate that each RNA must be individually investigated. An antisense transcript of the Wilms's tumor gene (a gene imprinted under certain circumstances) appears to enhance expression of the sense RNA (Moorwood *et al.*, 1998). Concerning the range of possible antisense RNA functions, it is interesting to note that an antisense RNA to basic fibroblast growth factor mRNA is thought to serve in two capacities: to act as the mRNA for a highly conserved protein of its own and to down-regulate growth factor expression. Several additional antisense RNAs contain open reading frames and may specify proteins.

When interpreting a report of a newly discovered antisense RNA, particularly one detected in eukaryotic cells, it is important to remember that terminology in this part of the field permits a molecule to be designated an "antisense RNA" on the basis of sequence information alone. There is no requirement that the RNA bind to its sense counterpart or alter expression of the sense RNA in any way. Furthermore, throughout the entire antisense field, there is no requirement that sense and antisense RNAs be transcribed from opposite strands of the same DNA, and thus they are not necessarily exact complements of each other.

The looseness in antisense terminology could be problematic. However, it serves a useful purpose, increasing the chances that meaningful similarities will be recognized. Such similarities illustrate the principles governing the behavior of antisense RNAs. Examples are selected from three areas: prokaryotic systems, virus-infected mammalian cells, and artificial

inhibitory RNAs. Antisense RNAs involved in RNA maturation, such as guide RNAs and snoRNAs, are not discussed further due to space limitations. However, the ability of guide RNAs to transfer genetic information is reflected in the function of the minus-strand viral RNAs, which are included; and the ability of snoRNAs to induce site-specific methylation is echoed in the gene-specific DNA methylation associated with some of the artificial inhibitory RNAs.

B. Artificial RNAs expanded the antisense field in unexpected directions

Some naturally occurring antisense RNAs are highly effective gene regulators. Their efficacy, and the conceptual simplicity of antisense-mediated gene ablation stimulated efforts to develop artificial antisense RNAs that could be used to inhibit specific genes in higher organisms and to confer resistance to micro-organisms. These efforts have already yielded commercial agricultural products, such as the transgenic Flavr Savr tomato. They have also revealed that it is sometimes possible to substitute a sense transcript for an antisense transcript and achieve the same level of target-gene inhibition. Because it is usually impossible for sense transcripts and their targets to form a perfect duplex containing more than about 7–12 bp, sense inhibition appears to be a manifestation of a novel regulatory pathway. It is important to learn the details of this pathway in order to gain insight into RNA function and to facilitate the development of more effective artificial RNAs for use in biotechnology and basic research.

C. Despite the diversity of antisense RNAs, four general principles account for most antisense effects

The first principle is that, above all else, antisense RNAs are ribonucleic acids. As such, they are endowed with a unique combination of properties. RNAs can store and transmit genetic information, just as DNA can. Moreover, naturally occurring RNAs readily form intricate three-dimensional structures and can produce catalytic active sites. RNAs are directly involved in protein synthesis at a variety of levels. Most RNAs are transcribed from DNA through a complex process involving *cis*-active promoter elements and many proteins. Nascent transcripts are converted into mature RNAs through an equally complex set of reactions. Regulation can occur at any of a number of points during transcription and subsequent processing. RNAs can be stable, or they can turn over rapidly. RNAs can readily move from the nucleus to the cytoplasm, and shuttle back and forth. They can form structural signals recognized by

proteins, and they can interact with other nucleic acids through complementary base pairing. These properties allow antisense RNAs to weave their way in and out of an enormous variety of cellular processes.

The second principle is that complementarity between an antisense RNA and a second nucleic acid is no guarantee that the two molecules will bind to each other. The tendency of antisense and target RNAs to form complexes, or to remain as separate molecules, is strongly influenced by their individual intramolecular structures. Potential nucleation sites can be prominently displayed, or virtually inaccessible. Complex formation is a bimolecular reaction whose rate is sensitive to concentration; the rate increases with increasing RNA concentration. The relationship between antisense RNA structure and function is illustrated most clearly by the antisense RNAs of prokaryotic systems, which are described in Sections II.A and II.B. Subcellular location also affects the probability that two RNAs will interact. Sense and antisense RNAs transcribed from the same genetic locus are more likely to encounter each other than RNAs transcribed from distant sites in the DNA. Similarly, two RNAs that accumulate in the same membrane-bound compartment are more likely to interact than those in separate compartments.

The third principle is that antisense activity is often mediated by proteins; these proteins must be identified and their modes of action characterized for antisense RNA function to be understood. Many different proteins bind to antisense RNAs and to the RNA–RNA duplexes they create. Depending on the protein and the nature of the duplex, binding can have a variety of effects. The same protein may catalyze a range of reactions, with the outcome determined by information encoded in the structure of the RNA–RNA duplex. Interactions between antisense RNAs and proteins are described in Sections II.D and III.C.

The fourth principle is that dsRNA can act as a signal. Mammalian cells recognize dsRNA as a sign that they, or their neighbors, are infected by a virus. Double-stranded RNA causes mammalian cells to enter an antiviral state. This response is mediated by a group of dsRNA-binding proteins, which make up a very sensitive dsRNA biosensor. There is growing evidence that dsRNA has symbolic value to cells from a variety of plants and animals. The potential of dsRNA to act as a signal is described in Sections III.A and IV.B–D and should be kept in mind when considering the possible biological effects of an antisense RNA.

D. Summary

Antisense RNAs have many roles. They can act as negative regulators of gene expression, induce interferon,

or direct RNA maturation. Antisense effects are strongly influenced by internal RNA structure and are often mediated by proteins. Artificial antisense RNAs have allowed new agricultural products to be developed and revealed unexpected roles of RNA in gene regulation.

II. ANTISENSE RNAS IN PROKARYOTIC SYSTEMS: INHIBITION BY DIRECT BINDING TO TARGET RNAs

A. The copy number of plasmid ColE1 is regulated by RNA I, an antisense transcript

RNA I of the *Escherichia coli* plasmid ColE1 was the first regulatory antisense RNA to be discovered. In 1981, Lacatena and Cesareni reported that base pairing between complementary regions of RNA I and RNA II inhibits plasmid replication. Because this system illustrates many principles of antisense RNA action it is discussed in detail.

As is typical of antisense reactions, binding between RNA I and RNA II is a bimolecular process. Its rate is concentration dependent. The concentration dependence of the RNA I–RNA II binding reaction is harnessed to achieve the desired biological effect—maintenance of plasmid copy number at a stable 10–20 copies per cell. Formation of the RNA I and RNA II complex inhibits plasmid DNA replication by preventing RNA II from maturing into the RNA primer required for DNA synthesis (for an excellent review of this system by a leading research group, see Eguchi *et al.*, 1991). RNA I is constitutively synthesized at a high rate and has a short half-life. Its concentration

reflects the number of template DNA molecules. When copies of the plasmid are numerous, RNA I concentration is high, binding to RNA II is favored, and plasmid DNA synthesis is inhibited. Conversely, when the plasmid DNA concentration is low, RNA I concentration falls, and plasmid replication is stimulated. Because RNA I contains regions complementary to the RNA II molecules produced by related plasmids, it provides the basis for plasmid compatibility and incompatibility. RNA I has no coding capacity.

Synthesis of RNA II is initiated 555 bases upstream from the origin of DNA replication. RNA I is perfectly complementary to 108 bases at the 5'-end of RNA II and is transcribed from the same region of the genome, but in the opposite direction. RNA I must bind RNA II shortly after RNA II synthesis is initiated. If binding is delayed, the nascent RNA II transcript forms structures that render it resistant to inhibition by RNA I. This competition between formation of the RNA I–RNA II complex and the RNA II self-structure means that antisense activity requires rapid association.

RNA I and RNA II interact through an intricate process whose individual steps are predetermined by the structures of the two RNAs. As illustrated in Fig. 5.1. RNA I has three stem-loop structures and a short tail at its 5'-end. The loops contain seven bases. Figure 5.1 also depicts RNA II, in a conformation that may exist in nascent RNA II transcripts. The secondary structures of RNA I and RNA II maximize the chances that they will form a bimolecular complex. Three sets of complementary bases are exposed in single-stranded loops. Bases making up these potential nucleation sites are displayed in structures somewhat similar to those that project the bases of tRNA anti-codons toward the

FIGURE 5.1 Binding of ColE1 RNA I to RNA II is a stepwise process. RNA I and RNA II interact through complementary sequences present in loops to form C^{**}. Pairing between the 5'-end of RNA I and RNA II is followed by a series of structural changes that culminate in the formation of a stable complex, C^S. Finally, RNA I hybridizes to RNA II throughout its entire length. Adapted from Eguchi *et al.* (1991).

mRNA codons. During nucleation, bases in corresponding loops of RNA I and RNA II interact weakly, evidently forming a limited number of bonds between bases in only one or two loops. The very unstable early intermediates can dissociate rapidly, or establish a "kissing complex," which can, in turn, produce the C** complex, a structure in which all three corresponding loops (reversibly) interact with each other.

The formation of C** can be facilitated by the plasmid-encoded protein, Rom (RNA-one-modulator), which binds to the kissing complex and reduces its equilibrium dissociation constant. The solution structure of a helix modeled after the RNA I-RNA II loop-loop helix was recently solved by nuclear magnetic resonance spectroscopy (Lee and Crothers, 1998). As expected from previous biochemical studies, all seven bases in the loops form complementary base pairs. The loop-loop helix partially stacks on the stem helices, producing a nearly linear structure. The loop-loop helix is bent toward the major groove, which is thereby narrowed. This bend, as well as phosphate clusters flanking the major groove, distinguish this helix from standard A-form RNA, perhaps accounting for the ability of Rom to recognize it. Conversion of C** to stable structures, such as C^s, begins with events occurring at the 5'-end of RNA I. If enough time elapses, the stable complex convert into full-length dsRNA molecules. However, inhibition can result from stable complex formation itself and does not require the generation of a complete duplex. Any lengthy dsRNA regions that form are likely to be rapidly degraded by the endonuclease RNase III.

B. Antisense RNAs in prokaryotic systems have many features in common

1. Antisense RNA structure

RNA I is only the first example of the many well-characterized antisense RNAs in prokaryotic systems. Four other representative antisense RNAs are depicted in Table 5.1 and their modes of action are presented. Prokaryotic antisense RNAs are typically small (65–100 bases), stable, noncoding RNAs, whose secondary structures contain one or more stem-loops (see Table 5.1). The loops usually contain 5–8 bases and often have sequences that are similar to each other. The stems of antisense RNA stemloop structures often contain unpaired nucleotides at precise locations. These "imperfections" protect the RNAs from cleavage by dsRNA-specific ribonucleases and also reduce the stability of the stems, allowing them to open up during binding to their target RNAs (Hjalt and Wagner, 1995).

2. Antisense and target RNAs associate through a stepwise binding process

Antisense and target RNAs interact through a stepwise process that proceeds from nucleation to stable complex formation. This process has been studied extensively in three systems: RNA I and RNA II of the plasmid ColE1, CopA and CopT of the plasmid R1 (CopT occurs in repA mRNA; see Table 5.1), and RNA-OUT and RNA-IN from the mobile genetic element IS10. The apparent second-order rate constants for pairing between these RNAs are in the range of $0.3\text{--}1.0 \times 10^6 \text{M}^{-1}\text{s}^{-1}$. In the binding reactions between RNA I and RNA II and between CopA and CopT, loop-loop interactions between antisense and target RNAs nucleate binding and formation of the kissing complex. In the binding reaction between RNA-OUT and RNA-IN, the first bonds form between bases in the loop of RNA-OUT and the 5'-end of RNA-IN, an RNA thought to have a relatively open structure. Rapid association appears to be a general requirement for efficient antisense activity. Because they mediate this early and rapid association, the initial base pairs are far more important to the overall binding process than their thermodynamic contribution to the final complex would suggest. Early intermediates are rapidly replaced by complexes containing more intermolecular base pairs. The final outcome of antisense binding depends on the system. Effects include termination of transcription, destabilization, and inhibition of translation. All known prokaryotic antisense RNAs are negative regulators of gene expression, although according to Wagner and Simons, "mechanisms for positive control are quite plausible" (Wagner and Simons, 1994).

Most, but not all, antisense RNAs are transcribed from overlapping gene sequences. As indicated in Table 5.1, mRNA-interfering complementary (micF) RNA is not closely linked to its target, ompF RNA. The duplex they form contains looped-out regions and noncanonical base pairs, in addition to conventional bonds (Delilhas *et al.*, 1997). This duplex helps to establish the lower limit of complementarity for an antisense-target RNA pair. Within the duplex, only 24 of 33 bases (73%) of micF RNA are Watson-Crick base-paired to nucleotides in ompF RNA.

C. Bioengineers hope to use the special features of naturally occurring antisense RNAs to develop effective artificial antisense RNAs

Engdahl and colleagues attempted to apply their knowledge of naturally occurring antisense RNAs to develop bioengineered antisense RNAs capable of

TABLE 5.1 Representative antisense RNAs of prokaryotic accessory DNA elements and bacterial DNA

System	Antisense RNA structure	Mode of action
Plasmid Plasmid R1 Antisense: CopA (91 bases) Target: CopT		CopA indirectly prevents synthesis of RepA, a protein required for plasmid replication, by pairing with CopT sequences in the polycistronic RNA that encodes RepA. Binding blocks the ribosome binding site of the tap gene, and prevents its translation, which is coupled to translation of the repA gene. Binding also yields duplexes which are RNase III substrates.
Phage Bacteriophage λ Antisense: oop RNA (77 bases) Target: cII mRNA		oop RNA binds to (55) bases at the 3'-end of the cII portion of the cII-O mRNA, creating an RNase III cleavage site, destabilizing the cII message, and thereby enhancing the burst size during induction.
Transposable element Insertion sequence IS10 Antisense: RNA OUT (70 bases) Target: RNA-IN		RNA-OUT binds to (35) nucleotides at the 5'-end of RNA-IN, transposase mRNA, preventing translation by blocking the ribosome binding site or by creating an RNase III cleavage site. Antisense inhibition increases as IS10 copy number increases, producing multicopy inhibition. IS10 is the mobile element of Tn10 (a tetracycline-resistance transposon).
Bacterial chromosome <i>Escherichia coli</i> Antisense: micF RNA (93 bases) Target: ompF mRNA		micF RNA is about 70% complementary to the 5'-end of ompF mRNA in the region of the ribosome binding site. Binding modulates production of OmpF, a major component of the <i>E. coli</i> outer membrane.

inhibiting selected target genes (Engdahl *et al.*, 1997). They tested antisense RNAs containing a recognition element resembling the major stem-loop of CopA and either a segment complementary to the ribosome binding site of the target RNA or a ribozyme. None of their antisense RNAs inhibited the target genes by more than 50%. They concluded, “we still have too

little insight into the factors that determine this property [the ability to rapidly associate] and, hence cannot yet tailor such structures to any chosen target sequence.” However, their study and similar studies by other investigators are helping to identify the structural features needed to produce effective artificial antisense RNAs for use in bacterial systems.

D. Proteins often mediate antisense RNA activity: RNase III is a prototypic dsRNA-binding protein

Important steps in several antisense systems are carried out by RNase III. Purified in 1968, RNase III was the first enzyme to be discovered that recognizes RNA–RNA duplexes as substrates. Like many other dsRNA-binding proteins, RNase III does not act exclusively on perfect duplexes. The varied interactions between RNase III and its substrates illustrate the range of functions that can be included in the repertoire of a single enzyme.

As illustrated in Fig. 5.2A, RNase III cleaves perfect RNA–RNA duplexes into short fragments averaging about 15 bases in length. Cuts are made across both strands of the duplex, at sites that are usually offset by one or two bases. This reaction shows no sequence specificity. Certain complexes of antisense and target RNAs are degraded by such randomly placed double-cleavages. In contrast, the 30S rRNA precursor is cut at four precise bonds. The rRNA precursor folds into a structure with two large stems, one topped by the

sequence of 16S rRNA, the other by 23S rRNA. RNase III cleaves each of these stems exactly twice at specific nucleotides, releasing rRNA intermediates. The stem flanking 23S rRNA is shown in Fig. 5.2B. The cleavage reactions carried out on the nearly perfect stems in the rRNA precursor resemble those carried out on perfect duplexes in certain respects, but not others. They are double-cleavages, but at predetermined locations. Surprisingly, RNase III also makes a series of precise cuts in the early mRNA precursor of bacteriophage T7 (Fig. 5.2C), even though this molecule contains no structures that bear an obvious similarity to perfect duplexes. Although the bacteriophage T7 cleavage sites lack the hallmark feature of dsRNA—a consecutive series of Watson–Crick bonds—they almost certainly contain noncanonical bonds that confer stability and allow them to fold into three-dimensional structures with features similar to dsRNA.

As a group, the RNase III cleavage sites demonstrate the subtlety of the interactions between dsRNA-binding proteins and RNA molecules. RNase III acts as a rampant random nuclease on dsRNA substrates. Duplexes are cleaved at multiple sites regardless of

FIGURE 5.2 Structural features of dsRNA regions direct RNase III cleavage. RNase III cleaves perfect RNA–RNA duplexes into fragments averaging 15 base pairs in length (A). In addition, it cuts the 30S ribosomal RNA precursor at four positions, releasing intermediates that will become the mature ribosomal RNAs. The double-cleavage site in the region 23S region (Bram *et al.*, 1980) is shown (B). Finally, RNase III cleaves certain complex RNA structures, such as those in the bacteriophage T7 early mRNA precursor at single sites. These complex structures are typically depicted as “bubbles” because they are devoid of Watson–Crick pairs; however, it is likely that they contain a precise array of non-canonical bonds and are not open loops (C).

their sequence; yet RNase III makes precise cleavages at sequence-specific sites in certain RNA precursor molecules. The structure of the RNA dictates the outcome of encounters with RNase III. The ability of single-stranded RNAs to exploit and sometimes to thwart dsRNA-specific enzymes is a significant survival factor for viruses, as illustrated by bacteriophage T7, and by the mammalian viruses discussed in the next section.

E. Summary

Naturally occurring antisense RNAs in prokaryotic systems are small, noncoding molecules whose structures facilitate rapid association with target RNAs. These antisense RNAs are much more than RNA molecules that happen to have sequences complementary to those of other RNAs. They are highly evolved machines designed to snare and entwine their targets. Inhibition can be a direct consequence of binding, or it can involve cellular proteins, especially endonucleases. RNase III is an endonuclease that cleaves RNA–RNA duplexes, such as those produced by certain antisense RNAs and their targets. Degradation is not the inevitable fate of an RNase III substrate. Depending on the structure of the duplex, RNase III can also introduce specific cleavages and promote RNA maturation.

III. ANTISENSE RNAs IN VIRUS-INFECTED MAMMALIAN CELLS: SIGNALS OF DANGER

A. dsRNAs are potent inducers of interferon and activators of antiviral defenses

Because the interferon response is central to mammalian antiviral defense, few antisense molecules can compete for significance with those producing the dsRNAs that induce interferon and otherwise contribute to the antiviral state. Despite the technical obstacles that make these dsRNAs difficult to study, they are analyzed here because of their importance to mammalian survival and because they illustrate the ability of dsRNA to act as a signal. The protective power of an intact interferon response is demonstrated by studies of transgenic mice deficient in either the type I or the type II interferon receptor. These mice rapidly succumb to viral infections that they would otherwise readily clear. For example, while the median lethal dose of intravenously administered vesicular stomatitis virus is normally in the range of 10^8 plaque-forming units, mutant mice lacking the type I IFN receptor die within 3–6 days after

receiving 30–50 units (Muller *et al.*, 1994). A functional interferon system raises the lethal dose of this virus 2 million-fold.

Mammalian cells have an extraordinarily sensitive mechanism for detecting dsRNA and for responding to dsRNA by synthesizing interferons. In 1977, Marcus and Sekellick reported that primary chick embryo cells are capable of responding to a single molecule of dsRNA. They exposed cells to defective interfering particles of vesicular stomatitis virus containing a covalently linked antisense–sense RNA molecule in a ribonucleoprotein complex. A single dsRNA molecule was presumed to form upon entry into the cell. Peak interferon titers were obtained in cultures incubated with 0.3 particles per cell. Both higher and lower doses of particles resulted in very marked reductions in interferon production, producing a bell-shaped dose–response curve. The data indicated that cells that attached two or more particles produced little or no interferon. Cells in the cultures exposed to the defective interfering particles entered a general antiviral state, as indicated by their resistance to a subsequent challenge with Sindbis virus. Control experiments ruled out the possibility that interferon induction was due to proteins in the particles.

In these experiments, cells responded to intracellular dsRNA. Cells also respond to exogenously applied dsRNA. This ability may allow cells to respond to dsRNA released from their moribund neighbors. A pharmaceutical form of dsRNA has been developed for intravenous delivery to virus-infected patients. When dsRNA acts as a danger signal, it is performing a function similar to that of unmethylated CpG-containing DNA. Such DNA is a strong immune stimulant and is interpreted by B-cells and cells of the innate immune system as a sign of microbial attack. Thus, two types of nucleic acid, dsRNA and unmethylated CpG-containing DNA, are central to mammalian defenses against infectious agents.

B. Viruses are thought to be the source of interferon-inducing antisense RNA and dsRNA, but hard evidence is very difficult to obtain

Conventional wisdom holds that the dsRNAs responsible for interferon induction are entirely of viral origin. However, as stated by Jacobs and Langland, “Actually identifying the potential sources of dsRNA in infected cells has in fact been problematic over the years” (Jacobs and Langland, 1996). The replication intermediates of RNA viruses contain both plus and minus RNAs, and are obvious potential sources of dsRNA. DNA viruses could generate dsRNA by aberrant

transcription or by transcription of overlapping genes encoded on opposite strands.

The lack of direct evidence concerning the identity of the interferon-inducing dsRNA reflects technical difficulties that make it nearly impossible to analyze the critical dsRNA molecules. Ironically, the cell's extreme sensitivity is a major problem; it sets a standard for dsRNA detection that existing molecular techniques cannot equal. RNA viruses generate relatively large quantities of complementary (minus) strands during the course of replication. Minus strands create a potential background problem because they can associate with sense strands during the extraction process. Particularly if the extraction is carried out in the presence of phenol, which catalyzes nucleic acid hybridization, the presence of viral dsRNA in extracts does not prove that it existed in cells.

Even when dsRNA can be shown to be present in cells, for example by the use of dsRNA-specific antibodies, questions remain about whether this dsRNA was accessible to the cell's dsRNA-sensing machinery. Magliano and colleagues demonstrated that the membrane-bound cytoplasmic vacuoles, called rubella virus "replication complexes," are virus-modified lysosomes (Magliano *et al.*, 1998). This compartmentalization may effectively hide the rubella virus dsRNA. Similar membranous structures have been described in other virus-infected cells. The sequestration of dsRNA may be a common viral defense strategy. Vaccinia virus, a DNA virus that produces large quantities of complementary transcripts, also produces proteins encoded by the E3L gene that bind dsRNA. This countermeasure is effective. Although vaccinia virus produces dsRNA, it is relatively resistant to interferon unless the E3L gene is mutated. Moreover, interferon resistance can be restored to mutant vaccinia by supplying RNase III (Shors and Jacobs, 1997), the bacterial endonuclease which destroys dsRNA. The ability of vaccinia to replicate in cells expressing RNase III suggests that the viral dsRNA is not required by the virus, but rather is a side product. It would be interesting to know whether RNase III-producing cells support the replication of mammalian RNA viruses, or if the RNA to RNA replication cycle of such viruses render them sensitive to this endonuclease. The replication intermediates of RNA bacteriophage contain little if any exposed dsRNA and are not sensitive to RNase III *in vivo*.

The studies of rubella virus and vaccinia virus illustrate the general point that the stronger the evidence that viral dsRNA exists inside infected mammalian cells, the stronger the evidence that the dsRNA is obscured in some way. These experiments indicate that viruses produce very little dsRNA that is exposed to the interferon sensing machinery, and suggest that

the RNAs reaching the dsRNA biosensor may not be mainstream viral RNAs required for replication. They also raise the possibility that viral dsRNA may not be the only sign cells use to detect viral infection. The high concentration of viral mRNA is a potential additional stigma. It has been proposed that higher plants have a surveillance system that recognizes and eliminates RNAs whose concentrations rise above threshold limits. This system has been associated with posttranscriptional gene silencing (see Section IV).

C. Double-stranded RNA-binding proteins contribute to the antiviral state

Double-stranded RNAs play two different roles in the interferon response. First, they stimulate interferon production and thus induce expression of at least 30 genes. Second, they interact with interferon-induced enzymes and thereby promote the antiviral state of the cell. Despite technical difficulties that impede direct analysis, it is possible to deduce some characteristics of these dsRNAs by studying the properties—length preferences, affinities, and concentrations—of the interferon-induced enzymes. Like dsRNA itself, at least one of these proteins, the interferon-induced RNA-dependent protein kinase (PKR), plays a dual role in the interferon response. PKR transduces the dsRNA signal, communicating to the nucleus that a virus is present. In addition, PKR and two other dsRNA-binding enzymes catalyze reactions that inhibit virus production.

1. The interferon-induced RNA-dependent protein kinase, PKR

PKR levels have been measured in human Daudi cells. Each cell contains about 5×10^5 molecules in the cytoplasm (mostly associated with ribosomes) and 1×10^5 in the nucleus (mostly in the nucleolus). Following interferon treatment, the PKR concentration rises three- to fourfold, with almost all of the increase occurring in the cytoplasm. IFN-treated cells contain approximately one molecule of PKR for each ribosome (Jeffrey *et al.*, 1995). Ribosomes compete with dsRNA for binding to PKR (Raine *et al.*, 1998). Ribosome-bound PKR may constitute a reserve supply that can be rapidly deployed without the need for new RNA or protein synthesis.

PKR binds to and is activated by long dsRNA molecules. As is true for many interactions between dsRNA-specific enzymes and perfect duplexes, there is no discernible sequence specificity for the reactions between PKR and dsRNA. Duplexes shorter than 30 base pairs do not bind stably to PKR and do not activate the

enzyme. Those longer than 30 base pairs bind with increasing efficiency, reaching a maximum at about 85 base pairs. The lack of sequence specificity allows the PKR to recognize dsRNAs regardless of their origins, satisfying a prerequisite for any broadbased antiviral response. The rather long optimal length of dsRNA makes PKR resistant to activation by the short and imperfect duplexes present in many cellular RNAs, including rRNAs. However, PKR's requirement for perfect duplexes is not absolute. Certain RNAs lacking extensive perfect duplexes activate PKR, including a cellular RNA recently identified by Petryshyn *et al.* (1997).

Binding to long dsRNA causes PKR to undergo an autophosphorylation reaction and become activated. This process displays a marked concentration dependence: PKR is activated by low concentrations of dsRNA (in the range of 10–100 ng/ml), but higher concentrations are less and less effective, giving rise to a bell-shaped activation curve. The shape of this curve indicates that PKR is optimally activated by a particular ratio of dsRNA to PKR. It also suggests that virus-infected cells do not contain high concentrations of accessible dsRNA. If they did, the PKR defense system would not function efficiently.

Once it has been activated, PKR phosphorylates a number of proteins, most notably the translation initiation factor eIF-2. This phosphorylation inhibits protein synthesis, thereby diminishing virus production. In addition, PKR appears to transduce the dsRNA signal, at least in part, by phosphorylating I- κ B, releasing and activating the transcription factor NF- κ B. Analysis of the interferon response is progressing rapidly, producing a picture of an intricate combinatorial cascade in which PKR activation by dsRNA is an early event in a series of reactions that culminates in the antiviral state.

PKR is a highly effective antiviral agent. Accordingly, several viruses have evolved strategies for neutralizing it. One of the best characterized of the anti-PKR viral products, and the one with the closest ties to dsRNA, is VAI RNA of adenovirus. In cells infected with mutant viruses deficient in VAI RNA synthesis, PKR is activated and protein synthesis comes to a halt. VAI RNA is an abundant RNA (10^8 copies per infected cell) that is about 160 bases long. It has enough similarity to *bona fide* dsRNA to bind to PKR, but lacks the structural features required for activation. Thus, it competitively inhibits activation by dsRNA.

2. The 2',5'-oligo(A) synthetases

The 2',5'-oligo(A) synthetases are activated upon binding to dsRNA molecules. They then polymerize

ATP into 2',5'-oligo(A), which in turn activates RNase L (a normally latent endonuclease), leading to mRNA degradation. Constitutive expression of 2',5'-oligo(A) synthetase has been shown experimentally to confer resistance to picorna virus infection.

In an attempt to determine the form of picorna virus RNA physically associated with the enzyme, Gribaudo and colleagues analyzed RNAs co-precipitating with 2',5'-oligo(A) synthetase extracted from encephalomyocarditis virus (EMCV)-infected HeLa cells (Gribaudo *et al.*, 1991). Precipitates contained both plus and minus EMCV RNAs. About 10% of the viral RNA was resistant to single-stranded RNA-specific ribonucleases, and thus potentially representative of preexisting dsRNA. However, the authors commented that this value might be "an overestimate resulting from the annealing of regions of complementary strands upon removing proteins which blocked the annealing." Providing further evidence that only a small percentage of the viral RNA was double-stranded *in vivo*, the synthetase prepared from these cells was not fully activated. Activation could be enhanced 20-fold by incubation with artificial dsRNA [poly(D)-poly(C)]. Because both adenovirus VAI RNA (Desai *et al.*, 1995) and heterogeneous nuclear RNA (Nilsen *et al.*, 1982) activate 2',5'-oligo(A) synthetases *in vitro*, extensive regions of perfect duplex structure are clearly not required for synthetase activation. Plus and minus EMCV RNAs may have stable structural elements capable of partially activating the synthetase, particularly in cells primed to respond. Further study is needed to determine whether both duplexes (composed of plus and minus viral RNAs) and free viral RNAs contribute to synthetase activation in picorna virus-infected cells.

3. The dsRNA adenosine deaminase, dsRAD

The dsRNA adenosine deaminase, dsRAD, catalyzes the C-6 deamination of adenosine to yield inosine. Deamination reduces the stability of dsRNAs. In conjunction with a ribonuclease specific for inosine-containing RNA (Scadden and Smith, 1997), dsRAD may play a role in viral defense. However, its contribution to viral defense is not as clearly established as that of the PKR kinase and the 2',5'-oligo(A) synthetases. Primarily a nuclear enzyme that is expressed in virtually all mammalian cells, dsRAD contributes to normal metabolism. It has also been implicated in the production of hypermutated measles virus RNAs during chronic infection of the central nervous system. Such chronic infection can lead to a fatal degenerative neurological disease, subacute sclerosing panencephalitis.

The substrate preferences of dsRAD are rapidly coming to light, and will clarify its biological functions when they are fully known. The deaminase has no clear *in vitro* sequence specificity for action on perfect dsRNA; however, some adenosines may be preferred. For maximum modification, intermolecular or intramolecular duplexes need to contain a minimum of 100 base pairs. From the standpoint of molecular structure, it is remarkable that this enzyme acts upon continuous duplex RNA. It is able to deaminate adenosines even though the C-6 amino group of adenosine lies in the deep and narrow major groove of standard A-form RNA, a space that is usually inaccessible to amino acid side-chains.

In addition to perfect duplexes, dsRAD acts on RNAs that lack extensive duplex structure. For example, it edits certain cellular pre-mRNAs, such as that of the glutamate-gated ion channel GluR. Like PKR and the 2',5'-oligo(A) synthetases, dsRAD binds to adenovirus VAI RNA *in vitro* (Lei *et al.*, 1998). In a manner similar to the assistance RNase III lends to bacteriophage T7, dsRAD aids the human hepatitis delta agent by deaminating a specific adenosine residue and carrying out an RNA editing event essential for the survival of this viroid-like pathogen. Exhibiting an additional similarity to RNase III, dsRAD behaves like one type of enzyme when interacting with long dsRNA molecules, in this case acting as a very robust and vigorous deaminase while it functions as a highly selective editing enzyme when interacting with single-stranded RNAs that have specific structural elements.

The dsRNA adenosine deaminase is clearly an enzyme with important cellular functions, and it is sometimes exploited by pathogens. Its role in antiviral defense is less clearly established, but the fact that its level rises following interferon treatment suggests that dsRAD contributes to the antiviral state.

D. Summary

Antisense RNAs play an important role in antiviral defenses by forming dsRNA. dsRNA is recognized by mammalian cells as a danger signal indicating that viral infection has occurred. A single molecule of dsRNA can induce interferon. Viruses often produce detectable amounts of dsRNA. However, in many cases, this dsRNA is obscured by other viral products. As a result, it has been difficult to pinpoint the actual dsRNA responsible for inducing the interferon response. Several cellular dsRNA-specific enzymes are induced by interferon and are thought to contribute to the antiviral state. Two of these enzymes degrade RNA, a third blocks protein synthesis. This

enzyme, the PKR, also contributes to the antiviral state by setting off a cascade that activates interferon synthesis.

IV. ARTIFICIAL RNAs, dsRNA, AND POSTTRANSCRIPTIONAL GENE SILENCING

A. Artificial sense, antisense, and dsRNAs place a spotlight on gene silencing

Just as Rutherford was unprepared for what happened when he shot alpha particles at a thin sheet of gold, biologists were unprepared for what occurred when they engineered plants to express sense transcripts of the *chalcone synthetase A* (*chA*) gene (van der Krol *et al.*, 1990; Napoli *et al.*, 1990). In many plants, both the transgene and the endogenous homolog of the transgene were silent, or co-suppressed. Thus, an attempt to overexpress genes involved in pigment formation resulted in plants with white flowers. These plants, and many studied subsequently, exhibit posttranscriptional gene silencing (PTGS), a condition in which specific RNA molecules are degraded.

The examples of PTGS in plants involve many different genes, plant species, and DNA constructs. It is believed that PTGS could be produced in all plant species with most endogenous genes. Furthermore, PTGS can be used to confer virus resistance to transgenic plants expressing sense transcripts of viral genes. The RNA affected by PTGS may be the product of a transgene, an endogenous plant mRNA, or a viral RNA. According to Balcombe, who reviewed hypotheses concerning the pathway leading to PTGS, all mechanisms require the production of an antisense RNA (Baulcombe, 1996). Evidence reveals that PTGS also occurs in nematodes (Fire *et al.*, 1998). At least in some cases, PTGS involves dsRNA molecules functioning as signals. In order to gain a full understanding of gene regulatory pathways and the biological role of RNA, it is critical to identify the molecular events leading to PTGS. To this end, PTGS is described here in three experimental settings.

B. Homology-dependent virus resistance occurs in transgenic plants

Viral genes have been transformed into a wide range of plant species to obtain viral protection. Results of these experiments support a two-phase model of homology-dependent resistance. In the first phase, viral and transgene RNA concentrations rise. After their combined concentration exceeds a threshold (or for some other

reason), a switch is triggered in a surveillance system and a factor capable of causing gene-specific RNA turnover is produced. Appearance of this factor—which is probably either a perfect or an imperfect RNA duplex—initiates the second (maintenance) phase. During the second phase, the factor moves from the inoculated leaf to other portions of the plant, causing systemic resistance (Voinnet and Baulcombe, 1997).

Like other forms of PTGS in plants, virus resistance is usually seen in only a fraction of the plants carrying a particular transgene. This variability suggests that PTGS results from a rare event. The level of virus resistance is also variable. In the most extreme cases, there is no detectable accumulation of the virus anywhere in the inoculated plant. In others, virus accumulates at least in the inoculated leaves. A plant showing intermediate resistance to tobacco etch virus (TEV) allowed the sequential events that take place during PTGS to be analyzed. This plant was initially susceptible to TEV and the transgene expressed high levels of viral sense transcripts. However, symptoms were attenuated in the (upper) leaves, which developed after inoculation. These new leaves contained little TEV RNA or RNA of the transgene. Such plants are said to have “recovered” (although the tissues showing “recovery” never developed symptoms in the first place) (Lindbo *et al.*, 1993; Goodwin *et al.*, 1996). This plant was resistant to challenge inoculation with a related virus, but was susceptible to infection by unrelated viruses, indicating that resistance was homology dependent.

Very similar events take place during certain natural viral infections, suggesting that homology-dependent virus resistance and natural resistance have common features. Ratcliff and colleagues demonstrated that *Nicotiana clevelandii* inoculated with tomato black ring nepovirus (strain W22) initially showed symptoms, and then recovered. Inoculated plants were resistant to challenge with a second inoculation of the same strain and were partially resistant to challenge with a related strain, BUK, which is 68% identical to W22. However, they were sensitive to an unrelated virus, potato virus X (Ratcliff *et al.*, 1997). Thus, in both homology-dependent virus resistance in transgenic plants and in certain natural viral infections, a factor is generated in highly infected tissues that moves to other parts of the plant, rendering them resistant. The specificity of these events strongly implicates a nucleic acid, almost certainly an RNA.

PTGS can be a two-way street, as illustrated by RNA viruses that have been engineered to contain inserts of nuclear genes. When such viruses replicate, they produce RNAs with sequences of the nuclear

genes and they inhibit expression of the nuclear gene. For example, the upper leaves of *N. benthamiana* inoculated with a recombinant tobacco mosaic virus containing part of the *phytoene desaturase* gene displayed a photobleaching effect, indicating that the desaturase gene had been inhibited (resulting in the loss of carotenoid-mediated protection) (Kumagai *et al.*, 1995). Because the RNAs of plant viruses are thought to have a strictly cytoplasmic location, these results indicate that either all steps of PTGS can take place in the cytoplasm or that the RNAs interact with DNA during cell division following breakdown of the nuclear envelope.

Waterhouse and colleagues produced strong evidence that dsRNA can trigger PTGS. They showed that *N. tabaccum* cv W38 engineered to express dsRNAs of the potato virus Y (PVY) protease gene were much more likely to acquire virus immunity than plants expressing either sense or antisense transcripts of this gene (Waterhouse *et al.*, 1998). As they pointed out, the efficacy of their constructs, which were designed to produce dsRNA in which both strands of the duplex originated from transgenes (rather than duplexes in which one strand originated from the transgene and the other strand was of viral origin), argues against conventional models of antisense action. Conventional models require pairing to take place between transcripts of transgenes and their targets, while the data of Waterhouse and colleagues indicate that constructs were much more effective when their transcripts were capable of forming dsRNA on their own. It will be interesting to learn what makes such constructs more effective than those expressing antisense RNA and to identify the cellular factors interacting with the dsRNA. Proteins will almost certainly be involved in this process. Changes at the DNA level, such as altered methylation, may also occur.

There are many reports of DNA methylation of transgenes associated with PTGS. For example, in tobacco plants displaying homology-dependent resistance and PTGS of a PVY transgene, the DNA of the transgene was methylated (Smith *et al.*, 1995). At the moment, the significance of DNA methylation is not clear. It may be a cause of homology-dependent PTGS, or it may be a consequence of it.

When one considers the impact RNA may have on DNA methylation patterns, it is interesting to consider the results of studies carried out on transgenic plants carrying defective viroid cDNAs. Viroids are circular RNAs that replicate through an RNA-to-RNA rolling-circle process in the nucleus. Inoculation of the transgenic plants with infectious viroid led to viroid replication and to specific methylation of the viroid cDNA sequences, even though this DNA was not the

template for the viroid RNA (Wassenegger *et al.*, 1994). Unfortunately, because viroid-infected nuclei contain both free viroid RNA and viroid replication intermediates (which may have dsRNA segments of unknown length), these experiments do not reveal whether single-stranded viroid RNA or double-stranded viroid RNA induced the DNA methylation.

C. Co-suppression of nuclear Genes in plants involves RNA–RNA duplexes

In studies paralleling those described above, Waterhouse and colleagues also compared the ability of various constructs to inhibit a $\Delta\beta$ -glucuronidase (GUS) reporter gene in rice. Some constructs were designed to produce single-stranded RNA transcripts, others to produce dsRNA. Based on their results, they concluded that co-suppression, like homology-dependent virus resistance, is triggered by dsRNA (Waterhouse *et al.*, 1998). Their conclusion is consistent with observations made by many earlier investigators who found that PTGS is more likely to occur in plants containing two tandem copies of a transgene arranged as inverted repeats, an organization favoring the production of transcripts capable of forming dsRNA.

Despite the strength of the evidence implicating a perfect duplex as the PTGS trigger, Metzloff and colleagues have developed a model that involves an imperfect duplex. Their model is based on the profiles of calcone synthetase-specific RNAs present in wild-type *Petunia* and in transgenic plants manifesting PTGS. They reported that white flowers of transgenic plants had little full-length poly(A)⁺ *chsA* RNA, but instead had characteristic mRNA fragments. They proposed that a self-sustaining degradation cycle is set in motion when sequences from the 3'-portion of an "aberrant" *chsA* transcript bind to partially complementary sequences in a second *chsA* RNA molecule, causing it to be cleaved and to release a new 3' fragment (Metzloff *et al.*, 1997). Significantly, fragments similar to those in the white-flowering transgenic plants accumulate in the white portions of a nontransgenic *Petunia* (Red Star) whose flowers have purple-white patterned flowers. This result shows that co-suppression uses steps of a preexisting control pathway. Eventually, the model proposed by Metzloff and colleagues will need to be reconciled with the evidence that perfect dsRNA can trigger PTGS. A consistent model may emerge when the events leading to the production of the "aberrant" transcript are understood in greater detail.

Further studies are also needed to define the role of DNA methylation in gene silencing. DNA methylation has been studied in *Petunia* and *Arabidopsis* manifesting

PTGS of the calcone synthetase gene. In purple *Petunia* flowers, an EcoRII site in the 3'-end of the endogenous genes only rarely contains a methylated cytosine, whereas in leaf DNA, these sites are frequently methylated. There is, therefore, a developmentally regulated loss of methylation at these sites. In transgenic plants with white flowers, this developmental change does not occur, and these sites are frequently methylated (Flavell *et al.*, 1998). To determine whether methylation is required for PTGS, Furner and colleagues studied transgenic *Arabidopsis* plants that carry a mutation in a gene required for DNA methylation. PTGS was reversed and expression of the *chs* transgene was restored in plants defective in DNA methylation, leading these investigators to conclude that "methylation is absolutely necessary" for PTGS (Furner *et al.*, 1998). Confirmation of this observation in another system will shed further light on the significance of DNA methylation.

D. dsRNA-induced homology-dependent posttranscriptional gene silencing takes place in *Caenorhabditis elegans*

RNA interference in nematodes was discovered by Guo and Kemphues, who found that antisense and sense transcripts yielded identical results when used to block gene expression in the maternal germ line (Guo and Kemphues, 1995). Fire and colleagues later demonstrated that dsRNA mediates PTGS in nematodes and that these worms have a transport system that allows dsRNA-mediated interference to move across cell membranes. On a mole-per-mole basis, they found that dsRNA transcripts were about 100 times more potent than either antisense or sense transcripts. Their initial experiments involved the *unc-22* gene, which encodes an abundant but nonessential myofilament protein. They injected a mixture of sense and antisense transcripts covering a 742-nucleotide segment of *unc-22* into the body cavity of adults and observed robust interference in the somatic tissues of the recipients and in their progeny broods. Only a few molecules of dsRNA were required per affected cell, suggesting that the dsRNA signal may have been amplified.

Several genes have been tested for susceptibility to dsRNA-mediated interference in addition to *unc-22*. The following observations have been made (Montgomery *et al.*, 1998; Tabara *et al.*, 1998; Fire *et al.*, 1998). First, PTGS effects are usually similar to those of null mutants, indicating that the target gene has been fully and selectively inhibited. However, some expression of the target gene can occur in dsRNA-treated worms. In some cases, suppression occurs in

only some cells. Second, mRNAs appear to be the targets of PTGS, rather than mRNA precursors. dsRNA segments corresponding to introns and promoter segments are not effective, as might be expected if precursors or the transcription process were the target. Furthermore, dsRNA covering upstream genes in polar operons have no effect on downstream genes, underscoring the conclusion that mRNAs, rather than precursors, are the target. In addition, cytoplasmic levels of target RNAs drop precipitously. Third, dsRNA-mediated interference is able to cross cellular boundaries. In fact, the dsRNA crosses cellular membranes so readily that it is possible to induce PTGS by feeding worms transgenic *Escherichia coli* expressing dsRNA covering the target gene (Timmons and Fire, 1998) or by soaking them in dsRNA—although neither of these approaches is as effective as microinjection. Fourth, PTGS passes into the F₁ generation; remarkably, Tabara and colleagues report that for certain genes, “interference can be observed to transmit in the germ line apparently indefinitely” (Tabara *et al.*, 1998).

E. The discovery of the importance of RNA interference is a major breakthrough

Growing evidence indicates that dsRNA is involved in gene regulation in higher organisms. In mammalian cells, dsRNA (whether applied exogenously or synthesized endogenously) induces interferon; in plants, dsRNA has been linked to homology-dependent virus resistance and to PTGS of both endogenous and transgenes; and in nematodes, dsRNA moves across cell boundaries and selectively inhibits gene expression. It was once thought that bioengineered antisense RNA would function by establishing Watson-Crick base pairs with target RNAs, thereby eliminating their function. It now appears that dsRNA mediates the effects of artificial RNAs in nematodes and in some cases of PTGS in higher plants. This dsRNA is evidently recognized by cellular factors that work in conjunction with it to destroy other RNAs of similar sequence. Most of the molecular intermediates of PTGS remain a mystery. However, DNA methylation frequently occurs during PTGS in plants and is thought to play an essential role by some investigators. When one considers the possible significance of PTGS for organisms other than vascular plants and worms, it is interesting to note that some of the mammalian genes that are subject to imprinting, a process associated with DNA methylation, express antisense transcripts (Ward and Dutton, 1998; Moorwood *et al.*, 1998; Rougeulle *et al.*, 1998; Reik and Constancia, 1997). As more studies are carried out on mammalian genes producing natural antisense

RNA and on mammalian cells synthesizing artificial antisense RNAs, mechanistic ties to PTGS may become apparent.

Continued exploration of phenomena such as PTGS, homology-dependent virus resistance, and co-suppression in plants; and RNA interference in nematodes have yielded important insights into the molecular biology of eukaryotes at the most basic level. It is now clear that many eukaryotic organisms—including humans, fruit flies, plants, and fungi—have the capacity to use short dsRNAs to (down) regulate expression of homologous target sequences. Several genes and gene products that contribute to this process have been identified. Their roles in a variety of biological processes, such as embryonic development, inhibition of transposon movement, and transcriptional silencing of chromosomal genes, remain areas of very active investigation. Gene regulation that is mediated by short dsRNA molecules is now most commonly referred to as “RNA silencing”. The short dsRNAs involved in RNA silencing are part of a much larger group of non-coding RNAs that perform both structural and regulatory functions—often through complementary base pair (antisense) interactions. A five-part “Special Section”—RNA Silencing and Noncoding RNA, *Science* (296, 1259–1273, 2002) provides an up-to-date and well-referenced review of RNA silencing, non-coding RNAs, and the biological functions they perform.

Several proteins involved in RNA silencing have been identified. In the “classical” RNA silencing degradative pathway, long dsRNA molecules are cleaved to short duplexes (21–23 nucleotides) by an RNase III-like enzyme called the Dicer, which leaves 2- to 3-nucleotide long 3' overhangs. These short dsRNAs may bind to 250–500 kD nuclease complex called RISC (RNA-induced silencing complex). The individual strands of the short dsRNAs associate with target RNAs through complementary base pairing, perhaps using an RNA helicase to separate from each other and thus gain access to sequences in the target mRNAs. The target RNAs are then cleaved by RISC. Should one of the individual strands of the short dsRNA bind to the target RNA in the absence of RISC, a structure results that may be amplified by an RNA dependent RNA polymerase, yielding additional long dsRNA that is a substrate for Dicer.

In the fields of genomics and biotechnology, short artificial dsRNAs are being introduced into cells to knock out target genes and thereby determine its function. Short dsRNAs can be more effective inhibitors than single-standard antisense oligonucleotides, and are being considered as potential therapeutic agents, as well as research tools. While initial experiments have produced impressive results and

demonstrate the RNA silencing can be obtained in mammalian tissue culture cells, the extent of target gene inhibition is variable. If RNA silencing molecules can be optimized, they may provide a shortcut for deletion mutagenesis and for large scale efforts to assign functions to individual genes. RNA silencing is one intriguing component of the larger and perennially eye-opening field of RNA biochemistry. Many more exciting discoveries can be expected as the full range of RNA's role in biology comes to light.

ACKNOWLEDGMENTS

I thank Dr. Jose Walewski, Mr. Decherd Stump, and Ms. Toby Keller for help with the manuscript. This work was supported in part by NIDDK (grants R01-DK52071 and P01-DK50795, project 2), the Liver Transplantation Research Fund, and the Division of Liver Diseases research funds.

Antiviral agents

Richard J. Whitley

The University of Alabama at Birmingham

GLOSSARY

acyclic purine nucleoside analog A molecule with the structure of the normal purine components of DNA or RNA but with the sugar ring cleaved open (acyclic).

alanine amino transferase An enzyme found in the liver and blood serum, the concentration of which is often elevated in cases of liver damage.

antiretroviral agent Any drug used in treating patients with human immunodeficiency virus (HIV) infection.

bioavailability The property of a drug to be absorbed and distributed within the body in a way that preserves its useful characteristics; for example, it is not broken down, inactivated, or made insoluble.

condyloma acuminatum Venereal warts.

conjunctivitis Inflammation of the conjunctiva or white of the eye.

EC₅₀ Concentration of a drug which produces a 50% effect, e.g., in virus yield.

enterovirus One of a group of viruses which infect the intestinal track.

Epstein-Barr virus A member of the herpesvirus family.

hantavirus pulmonary syndrome A pneumonia-like illness resulting from infection with hantavirus, a virus normally carried in rodents.

hepatotoxicity Liver toxicity.

hyperemia Literally excess blood; flushed, reddened, and engorged with blood.

interferon Any group of glycoproteins with antiviral activity.

interstitial nephritis An inflammation of the substance of kidney exclusive of the structure called the glomerulus.

leukopenia Deficiency in circulating white blood cells.

monotherapy Treatment with a single drug, contrasted with combination therapies with more than one drug at the same time.

mucocutaneous Refers to the skin where there is both exterior skin and mucus membranes, such as the borders of the mouth.

nephrotoxicity Kidney toxicity.

neuraminidase An enzyme, present on the surface of some viruses, which catalyzes the cleavage of a sugar derivative called neuraminic acid.

neuropathy Pathological changes in the nervous system.

papillomavirus A group of viruses causing warts of various kinds.

peptidomimetic A molecule having properties similar to those of a peptide or short protein.

pharmacokinetic Refers to the rates and efficiency of uptake, distribution, and disposition of a drug in the body.

phase III The final stage in testing of a new drug, after determination of its safety and effectiveness, in which it is tested on a broad range,

and large population of patients for comparison to existing treatments and to test for rare complications.

picornavirus A group of viruses with small RNA genomes, such as poliovirus.

prodrug A drug that is given in a form that is inactive and must be metabolized in the body to the active form.

stromal keratitis Inflammation of the deep layers of the cornea of the eye.

superficial punctate keratopathy Fine, spot-like pathological changes in the superficial layer of the cornea of the eye.

$t_{1/2}$ The time for reduction of some observed quantity, for example, the blood concentration of a drug, by 50%.

thrombocytopenia Deficiency of platelets, the blood-clotting agents, in the blood.

tubular necrosis Death of the tubule cells in the kidney.

uveitis Inflammation of the iris or related structures in the eye.

zoster Infection with varicella-zoster virus which leads to skin lesions on the trunk (usually) following the distribution of the sensory nerves; commonly called shingles.

Antiviral Agents are drugs that are administered for therapeutic purposes to humans with viral diseases. Importantly, many people are infected by viruses but only some develop disease attributed to these microbes. Antiviral agents used to treat these diseases are currently limited and only exist for the management of herpes simplex virus, varicella-zoster virus, cytomegalovirus, hepatitis B, hepatitis C, human immunodeficiency virus, respiratory syncytial virus, human papillomavirus, and influenza virus-related diseases.

Only a few antiviral agents of proven value are available for a limited number of clinical indications. Unique problems are associated with the development of antiviral agents. First, viruses are obligate intracellular parasites that utilize biochemical pathways of the infected host cell. Second, early diagnosis of viral infection is crucial for effective antiviral therapy because by the time symptoms appear, several cycles of viral multiplication usually have occurred and replication is waning. Third, since many of the disease syndromes caused by viruses are relatively benign and self-limiting, the therapeutic index, or ratio of efficacy to toxicity, must be extremely high in order for therapy to be acceptable.

Fortunately, molecular biology research is helping solve two of these problems. Enzymes unique to viral replication have been identified and, therefore, distinguish between virus and host cell functions. Unique events in viral replication are sites which serve as ideal targets for antiviral agents; examples include the thymidine kinase (TK) of herpes simplex virus (HSV) or protease of human immunodeficiency virus (HIV). Second, several sensitive and specific viral diagnostic methods are possible because of recombinant DNA technology [e.g., monoclonal antibodies, DNA hybridization techniques, and polymerase chain reaction (PCR)]. This article will synthesize knowledge of the existing antiviral agents as it relates to both pharmacologic and clinical properties.

I. THERAPEUTICS FOR HERPESVIRUS INFECTIONS

A. Acyclovir and valaciclovir

Acyclovir has become the most widely prescribed and clinically effective antiviral drug available to date. Valaciclovir, the L-valine ester prodrug of acyclovir, was developed to improve the oral bioavailability of acyclovir. Valaciclovir is cleaved to acyclovir by valine hydrolase which then is metabolized in infected cells to the active triphosphate of acyclovir.

1. Chemistry, mechanism of action, and antiviral activity

Acyclovir [9-(2-hydroxyethoxymethyl) guanine], a synthetic acyclic purine nucleoside analog, is a selective inhibitor of HSV-1 and -2 and varicellazoster virus (VZV) replication. Acyclovir is converted by

FIGURE 6.1 The mechanism of action of acyclovir. (A) activation and (B) Inhibition of DNA synthesis and chain termination.

virus-encoded TK to its monophosphate derivative, an event that does not occur to any significant extent in uninfected cells. Subsequent di- and triphosphorylation is catalyzed by cellular enzymes, resulting in acyclovir triphosphate concentrations 40–100 times higher in HSV-infected than in uninfected cells. Acyclovir triphosphate inhibits viral DNA synthesis by competing with deoxyguanosine triphosphate as a substrate for viral DNA polymerase, as illustrated in

Fig. 6.1. Because acyclovir triphosphate lacks the 3' hydroxyl group required for DNA chain elongation, viral DNA synthesis is terminated. Viral DNA polymerase is tightly associated with the terminated DNA chain and is functionally inactivated. Also, the viral polymerase has greater affinity for acyclovir triphosphate than does cellular DNA polymerase, resulting in little incorporation of acyclovir into cellular DNA. *In vitro*, acyclovir is most active against

HSV-1 (average $EC_{50} = 0.04 \mu\text{g/ml}$), HSV-2 ($0.10 \mu\text{g/ml}$), and VZV ($0.50 \mu\text{g/ml}$). Epstein-Barr virus (EBV) requires higher acyclovir concentrations for inhibition, and cytomegalovirus (CMV), which lacks a virus-specific TK, is relatively resistant.

Acyclovir is available in topical, oral, and intravenous preparations. Oral formulations include a 200-mg capsule, a 800-mg tablet, and suspension (200 mg/5 ml) and absorption of acyclovir results in 15–30% bioavailability. After multidose oral administration of 200 or 800 mg of acyclovir, the mean steady-state peak levels are approximately 0.57 and 1.57 $\mu\text{g/ml}$, respectively. Higher plasma acyclovir levels are achieved with intravenous administration. Steady-state peak acyclovir concentrations following intravenous doses of 5 or 10 mg/kg every 8 hr are approximately 9.9 and 20.0 $\mu\text{g/ml}$, respectively. The terminal plasma time for a 50% decrease in drug concentration ($t_{1/2}$) is 2 or 3 hr in adults with normal renal function. Acyclovir is minimally metabolized, and approximately 85% is excreted unchanged in the urine via renal tubular secretion and glomerular filtration.

Valaciclovir is only available as a tablet formulation and is metabolized nearly completely to acyclovir within minutes after absorption. Plasma levels of acyclovir, following 2 g of valaciclovir given three times a day by mouth, approximate 5 mg/kg administered every 8 h intravenously. Both acyclovir and valaciclovir must be dose adjusted if renal impairment exists.

2. Clinical indications

a. Genital herpes

First episode genital HSV infection can be treated with topical, oral, or intravenous acyclovir. Topical application is less effective than oral or intravenous therapy. Intravenous acyclovir is the most effective treatment for first-episode genital herpes and results in a significant reduction in the median duration of viral shedding, pain, and time to complete healing (8 versus 14 days) but is reserved for patients with systemic complications. Oral therapy (200 mg five times daily) is the standard treatment. Neither intravenous nor oral acyclovir treatment alter the frequency of recurrences.

While neither valaciclovir nor famciclovir have been evaluated in patients with primary genital herpes, their pharmacokinetic properties would predict efficacy. Many experienced physicians would preferentially use these drugs over acyclovir. The dose of valaciclovir is one gram t.i.d. for 7–10 days.

Recurrent genital herpes is less severe and resolves more rapidly than primary infection, offering a shorter time interval for successfully antiviral

chemotherapy. Topically applied acyclovir has no clinically beneficial effect. Orally administered acyclovir (200 mg five times daily or 400 mg three times daily) shortens the duration of virus shedding and time to healing (6 versus 7 days) when initiated within 24 h of onset, but the duration of pain and itching is not affected.

Oral acyclovir administration effectively suppresses frequently recurring genital herpes. Daily administration of acyclovir reduces the frequency of recurrences by up to 80%, and 25–30% of patients have no further recurrences while taking the drug. Successful suppression for as long as 3 years has been reported, with no evidence of significant adverse effects. Titration of acyclovir (400 mg twice daily or 200 mg two to five times daily) may be required to establish the minimum dose that is most effective and economical. Asymptomatic virus shedding can continue despite clinically effective acyclovir suppression, resulting in the possibility of person-to-person transmission.

Valaciclovir therapy of recurrent genital herpes (either 1 g or 500 mg twice a day) is clinically equivalent to acyclovir administered at either 200 mg three times daily or five times daily. It is also effective for suppression of recurrences when 1 g per day is administered.

b. Herpes labialis

Topical therapy for HSV-1 mouth or lip infections is of no clinical benefit. Orally administered acyclovir (200 or 400 mg five times daily for 5 days) reduces the time to loss of crust by approximately 1 day (7 versus 8 days) but does not alter the duration of pain or time to complete healing. Oral acyclovir therapy has modest clinical benefit but only if initiated very early after a recurrence. Valaciclovir is easier to administer and is given at 500 mg 2 \times day every 12 hours.

c. Immunocompromised host

HSV infections of the lip, mouth, skin, perianal area, or genitals may be more severe in immunocompromised patients. Clinical benefit from intravenous or oral acyclovir therapy is documented as evidenced by a significantly shorter duration of viral shedding and accelerated lesion healing. Acyclovir prophylaxis of HSV infections is of significant clinical value in severely immunocompromised patients, especially those undergoing induction chemotherapy or organ transplantation. Intravenous or oral acyclovir administration reduces the incidence of symptomatic HSV infection from 70 to 5–20%. A variety of oral dosing

regimens, ranging from 200 mg three times daily to 800 mg twice daily, have been used successfully.

d. Herpes simplex encephalitis

Acyclovir therapy (10 mg/kg every 8 h for 14–21 days) reduces mortality overall from 70 to 19%. Furthermore, 38% of acyclovir recipients returned to normal neurologic function.

e. Neonatal HSV infections

Acyclovir treatment of babies with disease localized to the skin, eye, or mouth yielded 100% survival, whereas 18 and 55% of babies with central nervous system (CNS) or disseminated infection died, respectively. For babies with HSV localized to the skin, eye, and mouth, 98% of acyclovir recipients developed normally 2 years after infection. For babies surviving encephalitis and disseminated disease, 43 and 57% of acyclovir recipients developed normally. The currently recommended intravenous dose is 20 mg/kg every 8 h for 14–21 days.

f. Varicella

Oral acyclovir therapy in normal children and adolescents with chicken pox shortens the duration of new lesion formation by about 1 day, reduces total lesion count, and improves constitutional symptoms. Therapy of older patients with chicken pox (who may have more severe manifestations) is indicated, whereas treatment of younger children must be decided on a case-by-case basis. The oral dose of acyclovir is 20 mg/kg/t.i.d. upto 800 mg p.o. t.i.d.

Acyclovir therapy of chicken pox in immunocompromised children substantially reduces morbidity and mortality. Intravenous acyclovir treatment (500 mg/m² of body surface area every 8 h for 7–10 days) improved the outcome, as evidenced by a reduction of VZV pneumonitis from 45 to <5%. Oral acyclovir therapy is not indicated for immunocompromised children with chicken pox; instead, treatment is with intravenous drug.

g. Herpes zoster

Intravenous acyclovir therapy of herpes zoster in the normal host produces some acceleration of cutaneous healing and resolution of pain—both acute neuritis and zoster-associated pain. Oral acyclovir (800 mg five times a day) administration results in accelerated cutaneous healing and reduction in the severity of acute neuritis. Oral acyclovir treatment of zoster

ophthalmicus reduces the incidence of serious ocular complications such as keratitis and uveitis. Valaciclovir (1 g three times daily for 7–10 days) is superior to acyclovir for the reduction of pain associated with shingles. Similar data established efficacy for famciclovir as shown below.

The increased frequency of significant morbidity in immunocompromised patients with herpes zoster highlights the need for effective antiviral chemotherapy. Intravenous acyclovir therapy significantly reduces the frequency of cutaneous dissemination and visceral complications of herpes zoster in immunocompromised adults. Acyclovir is the standard therapy at a dose of 10 mg/kg (body weight) or 500 mg/m² (body surface area) every 8 h for 7–10 days. Oral acyclovir therapy in immunocompromised patients with herpes zoster likely is effective, but valaciclovir is presumably superior.

3. Antiviral resistance

Resistance of HSV to acyclovir develops through mutations in the viral gene encoding TK via generation of TK-deficient mutants or the selection of mutants possessing a TK which is unable to phosphorylate acyclovir.

DNA polymerase mutants also have been recovered from HSV-infected patients. Acyclovir-resistant HSV isolates have been identified as the cause of pneumonia, encephalitis, esophagitis, and mucocutaneous infections, all occurring in immunopromised patients.

Acyclovir-resistant mutants have been described in the normal host but are uncommon. Acyclovir-resistant isolates of VZV have been identified much less frequently than acyclovir-resistant HSV but have been recovered from marrow transplant recipients and AIDS patients. The acyclovir-resistant VZV isolates all had altered or absent TK function but remained susceptible to vidarabine and foscarnet.

4. Adverse effects

Acyclovir and valaciclovir therapies are associated with few adverse effects. Renal dysfunction can occur but is relatively uncommon and usually reversible. A few reports have linked intravenous acyclovir use with CNS disturbances, including agitation, hallucinations, disorientation, tremors, and myoclonus.

An Acyclovir in Pregnancy Registry has gathered data on prenatal acyclovir exposures. Though no

significant risk to the mother or fetus has been documented, the total number of monitored pregnancies remains too small to detect any low-frequency teratogenic events.

B. Cidofovir

1. Chemistry, mechanism of action, and antiviral activity

Cidofovir, (S)-1-(3-hydroxy-2-phosphonomethoxypropyl) cytosine (HPMPC), is a novel acyclic phosphonate nucleoside analog and is used to treat acyclovir- and foscarnet-resistant HSV infections as well as CMV retinitis. The drug has a similar mechanism of action as the other nucleoside analog but employs cellular kinases to produce the active triphosphate metabolite. Activated HPMPC has a higher affinity for viral DNA polymerase, and therefore it selectively inhibits viral replication. The drug is less potent than ACV *in vitro*; however, *in vivo* HPMPC persists in cells for prolonged periods, increasing drug activity. In addition, HPMPC produces active metabolites with long half-lives (17–48 h), permitting once-weekly dosing. Unfortunately, HPMPC concentrates in kidney cells 100 times greater than in other tissues and produces severe proximal convoluted tubule nephrotoxicity when administered systemically. Attempts to limit nephrotoxicity include coadministration of probenecid with intravenous hydration, synthesis of cyclic congener prodrugs of HPMPC, and use of topical formulations. HPMPC has limited and variable oral bioavailability (2–26%) when tested in rats and, therefore, is administered intravenously.

2. Clinical indications

Cidofovir is licensed for treatment of CMV retinitis and has been used to treat acyclovir-resistant HSV infection. A treatment regimen of 5 mg/kg per week for 2 weeks followed by the same dose once weekly

provides superior benefit over lower maintenance doses. Probenecid and liberal intravenous hydration have been added to prevent significant nephrotoxicity. Because of nephrotoxicity, this regimen is less attractive than oral valganciclovir therapy.

3. Resistance

The development of resistance with clinical use is uncommon; however, mutations in CMV DNA polymerase can mediate altered susceptibility.

4. Adverse events

Nephrotoxicity is associated with the cidofovir administration, occurring in up to 30% of patients. Oral probenecid administration accompanies intravenously administered HPMPC in order to prevent significant nephrotoxicity.

C. Fomivirsen

Fomivirsen is the first antisense oligonucleotide licensed for the treatment of a viral disease.

1. Chemistry, mechanism of action, and antiviral activity

Fomivirsen (5'-GCG TTT GCT CTT CTT-3') is approved for the treatment of CMV retinitis. The IC_{50} against laboratory strains of CMV is about 0.37 μ M. Drug binds to the mrRNA of the immediate early 2 gene of CMV. Fomivirsen can only be administered by intravitreal injection. The pharmacokinetics of drug administration to the rabbit eye indicates a half-life of 62 hours.

2. Clinical indications

Fomivirsen delays progression of CMV retinitis when administered at a dosage of 330 μ g every other weeks on three occasions, followed by the same dose monthly. Drug is approved for patients intolerant to other medications.

3. Resistance

No isolates from humans have been reported as resistant to fomivirsen.

4. Adverse events

Increased intraocular pressure and inflammation have been reported as a major side effect in as many as 20% of patients.

D. Foscarnet

1. Chemistry, mechanism of action, and antiviral activity

Foscarnet, a pyrophosphate analog of phosphonoacetic acid has potent *in vitro* and *in vivo* activity against all herpesviruses and inhibits the DNA polymerase by blocking the pyrophosphate binding site, inhibiting the formation of the 3',5' phosphodiester bond between primer and substrate and preventing chain elongation. Unlike acyclovir, which requires activation by a virus-specific TK, foscarnet acts directly on the virus DNA polymerase. Thus, TK-deficient, acyclovir-resistant herpesviruses remain sensitive to foscarnet.

The oral bioavailability of foscarnet is poor; thus, administration is by the intravenous route. An intravenous infusion of 60 mg/kg every 8 h results in peak and trough plasma concentrations which are approximately 450–575 and 80–150 μM , respectively. The cerebrospinal fluid concentration of foscarnet is approximately two-thirds of the plasma level.

Renal excretion is the primary route of clearance of foscarnet, with >80% of the dose appearing in the urine. Bone sequestration also occurs, resulting in complex plasma elimination.

2. Clinical indications

Foscarnet is licensed for the treatment of CMV retinitis as well as HSV and VZV disease caused by acyclovir- or penciclovir-resistant viruses. Administration of foscarnet at 60 mg/kg every 8 h for 14–21 days followed by maintenance therapy at 90–120 mg/kg per day is associated with stabilization of retinal disease in approximately 90% of patients. However, as is with the case with ganciclovir therapy of CMV retinitis, relapse occurs.

Mucocutaneous HSV infections and those caused by VZV in immunocompromised hosts can be treated with foscarnet at dosages lower than that for the management of CMV retinitis. Foscarnet dosages of 40 mg/kg administered every 8 hr for 7 days or longer will result in cessation of viral shedding and healing of lesions in the majority of patients. However, relapses will occur which may or may not be amenable to acyclovir therapy.

3. Resistance

Isolates of HSV, CMV, and VZV have all been demonstrated to develop resistance to foscarnet both in the

laboratory and in the clinical setting. Isolates of HSV which are resistant to foscarnet have EC_{50} 100 $\mu\text{g}/\text{ml}$. These isolates are all DNA polymerase mutants.

4. Adverse effects

Although foscarnet has significant activity in the management of herpesvirus infections, nephrotoxicity, including acute tubular necrosis and interstitial nephritis, can occur. Metabolic aberrations of calcium, magnesium, phosphate, and other electrolytes are associated with foscarnet administration and warrant careful monitoring. Symptomatic hypocalcemia and resultant seizures are the most common metabolic abnormality. Increases in serum creatinine will develop in one-half of patients who receive medication but usually are reversible after cessation. Other CNS side effects include headache (25%), tremor, irritability, and hallucinations.

E. Ganciclovir and valganciclovir

1. Chemistry, mechanism of action, and antiviral activity

Ganciclovir [9-(1,3-dihydroxy-2-propoxymethyl) guanine] (Cytovene) has enhanced *in vitro* activity against all herpesviruses as compared to acyclovir, including an 8–20 times greater antiviral activity against CMV. Like acyclovir, the activity of ganciclovir in herpesvirus-infected cells depends on phosphorylation by virus-induced TK. Also like acyclovir, ganciclovir monophosphate is further converted to its di- and triphosphate derivatives by cellular kinases. In cells infected by HSV-1 or -2, ganciclovir triphosphate competitively inhibits the incorporation of guanosine-triphosphate into viral DNA. Ganciclovir triphosphate is incorporated at internal and terminal sites of viral DNA, inhibiting DNA synthesis. The mode of action of ganciclovir against CMV is mediated by a protein kinase, UL-97, that efficiently promotes the obligatory initial phosphorylation of ganciclovir to its monophosphate.

The oral bioavailability of ganciclovir is poor (5–7%). Peak plasma levels are approximately 1.0 µg/ml after administration of 1 g every 6 h. Intravenous administration of a standard dose of 5 mg/kg will result in peak and trough plasma concentrations of 8–11 and 0.5–1.2 µg/ml, respectively. Concentrations of ganciclovir in biologic fluids, including aqueous humor and cerebrospinal fluid (CSF), are less than plasma levels. The plasma elimination $t_{1/2}$ is 2–4 h for individuals with normal renal function. The kidney is the major route of clearance of the drug, and therefore, impaired renal function requires adjustment of dosage. Valganciclovir is orally bioavailable (approximately 60%) and is rapidly converted to ganciclovir after absorption. It is currently in clinical development.

Valganciclovir, L-valine, 2-[2-amino-1,6-dihydro-6-oxo-9H-purin-9-yl)methoxy]-3-hydroxypropyl ester, is metabolized completely to ganciclovir; thus, it has the same spectrum of activity and mechanism of activity as the parent compound.

2. Clinical indications

a. HIV-infected patients

Ganciclovir has been administered to large numbers of patients with AIDS having CMV retinitis. Most patients (78%) experience either improvement or stabilization of their retinitis based on fundoscopic exams compared to historical controls. Induction therapy is usually at a dosage of 5.0 mg/kg twice a day given intravenously for 14–21 days. Maintenance therapy is essential. Median time to relapse for patients receiving no maintenance therapy averages 47 days. Maintenance therapy of 25–35 mg/kg per week significantly lengthens median time to relapse to 105 days. Virtually every patient treated will experience either a cessation or reduction of plasma viremia. Visual acuity usually stabilizes at pretreatment levels but rarely improves dramatically. Relapse occurs quickly in the absence of maintenance therapy but usually occurs eventually, even in patients receiving maintenance therapy (5 mg/kg for 5–7 days per week). The significance of bone marrow toxicity must be taken into consideration since 30–40% of patients develop neutropenia. Benefit has been reported with the use of ganciclovir for the treatment of other CMV infections, particularly in those involving the gastrointestinal tract.

Ganciclovir can be administered orally for prevention of CMV disease and retinitis in patients with AIDS. The utilization of ganciclovir at dosages of 1 g three to six times daily, following intravenous

induction therapy, provides a sustained period prior to the next episode of reactivated retinitis at similar, albeit less (but not significantly less) intervals as when drug is given intravenously.

Valganciclovir is comparable to ganciclovir for the treatment of CMV retinitis. The dose is 900 mg twice daily for 3 weeks followed by 900 mg once daily.

b. Transplant recipients

Prophylaxis and preemptive therapy of CMV infections in high-risk transplant recipients is common. Both prevention and therapy of CMV infection of the lung are amenable to ganciclovir therapy. Ganciclovir of CMV pneumonia in conjunction with CMV immune globulin is therapeutically beneficial. Ganciclovir has been administered in anticipation of CMV disease to bone marrow transplant recipients (preemptive therapy). Several clinical trials utilizing different designs (e.g., initiation of ganciclovir after engraftment versus at the time of documentation of infection by bronchial alveolar lavage but in the absence of clinical symptomatology) have established the effectiveness of ganciclovir in preventing CMV pneumonia and reducing mortality during the treatment period. The utilization of ganciclovir in these circumstances has support among transplant physicians; however, long-term survival benefit (>120 days) is not apparent.

Valganciclovir is under investigation in organ transplant recipients.

3. Resistance

Resistance to CMV is associated with a deteriorating clinical course. Two mechanisms of resistance to ganciclovir have been documented: (i) the alteration of protein kinase gene, UL-97, reduces intracellular phosphorylation of ganciclovir, and (ii) point mutations in the viral DNA polymerase gene. Resistance is associated with decreased sensitivity up to 20-fold.

4. Adverse effects

The most important side effects of ganciclovir therapy are the development of neutropenia and that of thrombocytopenia. Neutropenia occurs in approximately 24–38% of patients. The neutropenia is usually reversible with dosage adjustment of ganciclovir, including withholding of treatment. Thrombocytopenia occurs in 6–19% of patients.

Ganciclovir has gonadal toxicity in animal models, most notably as a potent inhibitor of spermatogenesis. It causes an increased incidence of tumors in the preputial gland of male mice, a finding of unknown

significance. As an agent affecting DNA synthesis, ganciclovir has carcinogenic potential.

F. Idoxuridine and trifluorothymidine

1. Chemistry, mechanism of action, and antiviral activity

Idoxuridine (5-iodo-2'-deoxyuridine) and trifluorothymidine (trifluridine, Viroptic) are analogs of thymidine. When administered systemically, these nucleosides are phosphorylated by both viral and cellular TK to active triphosphate derivatives which inhibit both viral and cellular DNA synthesis. The result is antiviral activity but also sufficient host cytotoxicity to prevent the systemic use of these drugs. The toxicity of these compounds is not significant when applied topically to the eye in the treatment of HSV keratitis. Both idoxuridine and trifluorothymidine are effective and licensed for treatment of HSV keratitis. Topically applied idoxuridine or trifluorothymidine will penetrate cells of the cornea. Low levels of drugs can be detected in the aqueous humor.

2. Clinical indications

Trifluorothymidine is the most efficacious of these compounds. These agents are not of proven value in the treatment of stromal keratitis or uveitis, although trifluridine is more likely to penetrate the cornea and, ultimately, may prove beneficial for these conditions.

3. Resistance

Little effort has been directed to evaluating HSV isolates obtained from the eye, in large part because of the difficulty in accomplishing this task.

4. Adverse effects

The ophthalmic preparation of idoxuridine and trifluridine causes local irritation, photophobia,

edema of the eyelids, and superficial punctate keratopathy.

G. Penciclovir and famciclovir

1. Chemistry, mechanism of action, and antiviral activity

A new member of the guanine nucleoside family of drugs is famciclovir [9-(4-hydroxy-3-hydroxymethyl-but-1-yl) guanine; Famvir], the prodrug of penciclovir. Penciclovir does not have significant oral bioavailability (<5%), but famciclovir is orally bioavailable (approximately 77%) and has a good therapeutic index for the therapy of both HSV and VZV infections. Famciclovir is the diacetyl ester of 6-deoxy penciclovir. When administered orally, it is rapidly converted to penciclovir. The spectrum of activity of penciclovir is similar to that of acyclovir. Penciclovir is phosphorylated more efficiently than acyclovir in HSV- and VZV-infected cells. Host cell kinases phosphorylate both penciclovir and acyclovir to a small but comparable extent. The preferential metabolism in HSV and VZV-infected cells is the major determinant of its antiviral activity. Penciclovir triphosphate has, on average, a 10-fold longer intracellular half-life than acyclovir triphosphate in HSV-1, HSV-2, and VZV-infected cells after drug removal. Penciclovir triphosphate is formed at sufficient concentrations to be an effective inhibitor of viral DNA polymerase, albeit at a lower K_i than that of acyclovir triphosphate. Both compounds have good activity against HSV-1, HSV-2, and VZV. The activity of penciclovir *in vitro*, like acyclovir, is dependent on both the host cell and the assay (plaque reduction, virus yield, and viral DNA inhibition). The mean penciclovir $EC_{50} \pm$ standard deviation for HSV-1 in MRC-5, HEL, WISH, and W138 cells is 0.4 ± 0.2 , 0.6 ± 0.4 , 0.2 ± 0.2 , and $1.8 \pm 0.8 \mu\text{g/ml}$, respectively. For HSV-2, similar levels of activity in the identical cell lines are 1.8 ± 0.6 , 2.4 ± 2.5 , 0.8 ± 0.1 , and $0.3 \pm 0.2 \mu\text{g/ml}$, respectively. These assays utilize a plaque reduction procedure. In virus yield reduction assays, inhibition of VZV replication in MRC-5 cells is between 3.0 and 5.1 $\mu\text{g/ml}$, values virtually identical to those of acyclovir. Penciclovir, like acyclovir, is

relatively inactive against CMV and EBV. Penciclovir is also active against hepatitis B.

Conversion of famciclovir to penciclovir occurs at two levels. The major metabolic route of famciclovir is de-acetylation of one ester group as the prodrug crosses the duodenal barrier of the gastrointestinal tract. The drug is transported to the liver via the portal vein where the remaining ester group is removed and oxidation occurs at the sixth position of the side chain, resulting in penciclovir, the active drug. The first metabolite which appears in the plasma is almost entirely the de-acetylated compound, with little or no parent drug detected. Thus, the major metabolite of famciclovir is penciclovir. Pharmacokinetic parameters for penciclovir are linear over famciclovir oral dose ranges of 125–750 mg. Penciclovir is eliminated rapidly and almost unchanged by active tubular secretion and glomerular filtration by the kidneys. The elimination $t_{1/2}$ in healthy subjects is approximately 2 h.

2. Clinical indications

Famciclovir is available in an oral preparation. Penciclovir is available for topical therapy (Denavir).

a. Herpes zoster

Famciclovir (250, 500, or 750 mg three times a day) therapy is equivalent to the standard acyclovir treatment and superior to no therapy of herpes zoster for cutaneous healing, and in a subgroup analysis it accelerated resolution of pain (zoster-associated pain).

b. Genital HSV infection

Studies of patients with recurrent genital HSV infection (either intravenous penciclovir or oral famciclovir therapy) indicate beneficial effects in acceleration of all clinical parameter (e.g., pain, virus shedding, and duration). Famciclovir is given twice daily (125, 250 or 500 mg twice daily for 5 days). Famciclovir therapy on recurring HSV infections of immunocompromised hosts also is effective as suppressive therapy.

c. Herpes labialis

Topical application of penciclovir (Denavir) accelerates lesion healing (1 day) and resolution of pain. It is available over-the-counter in many countries.

3. Resistance

Herpes simplex virus and VZV isolates resistant to penciclovir have been identified in the laboratory. These isolates have similar patterns of resistance as

those of acyclovir. Namely, resistance variants can be attributed to alterations or deficiencies of TK and DNA polymerase.

4. Adverse effects

Therapy with oral famciclovir is well tolerated, being associated only with headache, diarrhea, and nausea—common findings with other orally bioavailable antiviral agents. Preclinical studies of famciclovir indicated that chronic administration was tumorigenic (murine mammary tumors) and causes testicular toxicity in other rodents.

H. Vidarabine

1. Chemistry, mechanism of action, and antiviral activity

Vidarabine (vira-A, adenine arabinoside, and 9D-arabinofuranosyl adenine) is active against HSV, VZV, and CMV. Vidarabine is a purine nucleoside analog that is phosphorylated intracellularly to its mono-, di-, and triphosphate derivatives. The triphosphate derivative competitively inhibits DNA dependent DNA polymerases of some DNA viruses approximately 40 times more than those of host cells. In addition, vira-A is incorporated into terminal positions of both cellular and viral DNA, thus inhibiting elongation. Viral DNA synthesis is blocked at lower doses of drug than is host cell DNA synthesis, resulting in a relatively selective antiviral effect. However, large doses of vira-A are cytotoxic to dividing host cells.

The benefit demonstrated in initial placebo-controlled clinical trials of this drug was a major impetus for the development of antiviral therapies. However, because of poor solubility and some toxicity, it was quickly replaced by acyclovir in the physician's armamentarium. Today, it is no longer available as an intravenous formulation. Vidarabine should be recognized historically as the first drug licensed for systemic use in the treatment of a viral infection.

2. Clinical indications

Vidarabine is only available as a topical formulation for ophthalmic administration.

3. Resistance

Studies of resistance to vidarabine have not been pursued.

4. Adverse effects

Ocular toxicity consists of occasional hyperemia and increased tearing, both of low incidence.

II. THERAPEUTICS FOR RESPIRATORY VIRUS INFECTIONS

A. Amantadine and rimantadine

1. Chemistry, mechanism of action, and antiviral activity

Amantadine (1-adamantane amine hydrochloride; Symmetrel) is a tricyclic amine which is effective against all influenza A variants. Amantadine has a narrow spectrum of activity, being useful only against influenza A infections. Rimantidine is the α -methyl derivative of amantadine (α -methyl-1-adamantane methylamine hydrochloride). Rimantidine is 5- to 10-fold more active than amantadine and has the same spectrum of activity, mechanism of action, and clinical indications. Rimantadine is slightly more effective against type A viruses at equal concentrations. The mechanism of action of these drugs relates to the influenza A virus M2 protein, a membrane protein which is the ion channel for this virus. By interfering with the function of the M2 protein, amantadine and rimantidine inhibit the acid-mediated association of the matrix protein from the ribonuclear protein complex within endosomes. This event occurs early in the viral replicate cycle. The consequences of this drug are the potentiation of acidic pH-induced conformational changes in the viral hemagglutinin during its intracellular transport.

Absorption of rimantadine is delayed compared to that of amantadine, and equivalent doses of rimantadine produce lower plasma levels compared to amantadine, presumably because of a larger volume of distribution. Both amantadine and rimantadine are absorbed after oral administration. Amantadine is excreted in the urine by glomerular filtration and, likely, tubular secretion. It is unmetabolized. The plasma elimination, $t_{1/2}$, is approximately 12–18 h in individuals with normal renal function. However, the elimination, $t_{1/2}$, increases in the elderly with impaired creatinine clearance. Rimantadine is extensively metabolized following oral administration, with an elimination $t_{1/2}$ which averages 24–36 h. Approximately 15% of the dose is excreted unchanged in the urine.

2. Clinical indications

Amantadine and rimantadine are licensed both for the chemoprophylaxis and treatment of influenza A infections. The efficacy of amantadine and rimantadine when used prophylactically for influenza A infections averages 70–80% (range, 0–100%), which is approximately the same as with influenza vaccines. Effectiveness has been demonstrated for prevention of both experimental (i.e., artificial challenge) and naturally occurring infections for all three major subtypes of influenza A. Because of a lower incidence of side effects associated with rimantadine, it is used preferentially. Rimantadine can be given to any unimmunized member of the general population who wishes to avoid influenza A, but prophylaxis is especially recommended for control of presumed influenza outbreaks in institutions housing high-risk persons. High-risk individuals include adults and children with chronic disorders of the cardiovascular or pulmonary system requiring regular follow-up or hospitalization during the preceding year as well as residents of nursing homes and other chronic-care facilities housing patients of any age with chronic medical conditions.

These drugs are also effective for the treatment of influenza A. All studies showed a beneficial effect on the signs and symptoms of acute influenza as well as a significant reduction in the quantity of virus in respiratory secretions at some time during the course of infection. Because of the short duration of disease, therapy must be administered within 48 h of symptom onset to show benefit.

3. Resistance

Rimantadine-resistant strains of influenza have been isolated from children treated for 5 days. There have

been subsequent reports of rimantadine-resistant strains being transmitted from person to person and producing clinical influenza. Development of resistance of influenza A viruses is mediated by single nucleotide changes in RNA segment 7, which results in amino acid substitutions in the transmembrane of the M2 protein. Obviously, amantadine and rimantadine share cross-resistance.

4. Adverse effects

Amantadine is reported to cause side effects in 5–10% of healthy young adults taking the standard adult dose of 200 mg/day. These side effects are usually mild and cease soon after amantadine is discontinued, although they often disappear with continued use of the drug. Central nervous system side effects, which occur in 5–33% of patients, are most common and include difficulty in thinking, confusion, lightheadedness, hallucinations, anxiety, and insomnia. More severe adverse effects (e.g., mental depression and psychosis) are usually associated with doses exceeding 200 mg daily. About 5% of patients complain of nausea, vomiting, or anorexia. Rimantadine appears better tolerated. Side effects associated with rimantadine administration are significantly less than those encountered with amantadine, particularly of the CNS. Rimantadine has been associated with exacerbations of underlying seizure disorders.

B. Oseltamivir

1. Chemistry, mechanism of action, and antiviral activity

Oseltamivir [ethyl (3R,4R,5S)-4-acetomido-5-amino-3-(1-ethylpropoxy)-1-cyclohexene-1-carboxylate] is a selective neuroaminidase inhibitor. It inhibits both influenza A and B virus at concentrations of 2 nM. Drug inhibits viral replication by targeting the neuraminidase protein via binding in a competitive fashion to the enzyme, rendering the virus incapable of reproducing. Because it has activity against influenza B, it has an advantage over the adamantanes. It has no activity against any other virus.

2. Clinical indications

Oseltamivir is licensed for the treatment and prevention of influenza A and B infections for individuals 2 years of age and older. Clinical trials indicate 30% acceleration in resolution of clinical symptoms. In pediatric studies, treatment accelerates disease resolution and is associated with a significantly decreased incidence of otitis media and antibiotic

usage by 30% to 40%. Prophylactic efficacy is reported to be 75% to 85%.

3. Resistance

Mutations in the neuraminidase have been detected rarely in patients exposed to medication. In clinical studies, 1.3% to 8.6% of posttreatment isolates have altered susceptibility to oseltamivir. In vitro, the emergence of a resistant variant occurs with the substitution of a lysine for the conserved arginine at amino acid 292 of the neuraminidase.

4. Adverse events

Oseltamivir is generally well tolerated. Nausea with or without vomiting occurs in about 10% of the patients. Food alleviates this side effect.

C. Zanamivir

1. Chemistry, mechanism of action, and antiviral activity

Zanamivir (5-acetylamino-4-[aminoiminomethyl-amino]-2,6-anhydro-3,4,5-trideoxy-D-glycero-D-galactonon-2-enonic acid) is a neuraminidase inhibitor. It binds competitively to influenza neuraminidase, habiting both influenza A and B. Influenza neuraminidase catalyzes the cleavage of the terminal sialic acid attached to glycolipids and glycoproteins. The oral bioavailability of zanamivir is poor, about 2%, thus it is only available as an inhaled medication.

2. Clinical indications

Zanamivir is licensed for the treatment and prevention of influenza A and B infections in patients over 7 years of age. In clinical trials, treatment reduced the duration of symptoms from 6 to 5 days and symptom scores by about 44%. The prophylactic efficacy of zanamivir is about 80%.

3. Resistance

Resistance is an uncommon occurrence in clinical trials, occurring no more frequently than in 1% of exposed patients. The site of mutation is that where drug binds the neuraminidase.

4. Adverse events

Most adverse effects are related to the respiratory tree. These include rhinorrhea and, rarely, bronchospasm.

Nausea and vomiting have been reported in less than 3%.

D. Ribavirin

1. Chemistry, mechanism of action, and antiviral activity

Ribavirin (α -methyl-1-adamantane methylamine hydrochloride) has antiviral activity against a variety of RNA and DNA viruses. Ribavirin is a nucleoside analog whose mechanisms of action are poorly understood and probably not the same for all viruses; however, its ability to alter nucleotide pools and the packaging of mRNA appears important. This process is not virus specific, but there is a certain selectivity in that infected cells produce more mRNA than noninfected cells. A major action is the inhibition by ribavirin-5'-monophosphate of inosine monophosphate dehydrogenase, an enzyme essential for DNA synthesis. This inhibition may have direct effects on the intracellular level of GMP; other nucleotide levels may be altered, but the mechanisms are unknown. The 5'-triphosphate of ribavirin inhibits the formation of the 5'-guanylation capping on the mRNA of vaccinia and Venezuelan equine encephalitis viruses. In addition, the triphosphate is a potent inhibitor of viral mRNA (guanine-7) methyltransferase of vaccinia virus. The capacity of viral mRNA to support protein synthesis is markedly reduced by ribavirin. Of note, high concentrations of ribavirin also inhibit cellular protein synthesis. Ribavirin may inhibit influenza A RNA-dependent RNA polymerase.

Ribavirin can be administered orally (bioavailability of approximately 40–45%) or intravenously. Aerosol administration has become standard for the treatment of respiratory syncytial virus (RSV) infections in children. Oral doses of 600 and 1200 mg result in peak plasma concentrations of 1.3 and 2.5 $\mu\text{g}/\text{ml}$, respectively. Intravenous dosages of 500 and 1000 mg result in 17 and 24 $\mu\text{g}/\text{ml}$ plasma concentrations, respectively. Aerosol administration of ribavirin results in plasma levels which are a function of the duration of

exposure. Although respiratory secretions will contain milligram quantities of drug, only microgram quantities (0.5–3.5 $\mu\text{g}/\text{ml}$) can be detected in the plasma.

The kidney is the major route of clearance of drug, accounting for approximately 40%. Hepatic metabolism also contributes to the clearance of ribavirin. Notably, ribavirin triphosphate concentrates in erythrocytes and persists for a month or longer. Likely, the persistence of ribavirin in erythrocytes contributes to its hematopoietic toxicity.

2. Clinical indications

a. Respiratory syncytial virus

While ribavirin is licensed for the treatment of carefully selected, hospitalized infants and young children with severe lower respiratory tract infections caused by RSV, it is no longer used. Use of aerosolized ribavirin in adults and children with RSV infections reduced the severity of illness and virus shedding. In patients receiving 8 or more hours of continuous therapy, the mean peak level in tracheal secretions may be 100 times greater than the minimum inhibitory concentration preventing RSV replication *in vitro*. The use of ribavirin for the treatment of RSV infections is controversial and remains discretionary. It is under study for prevention of RSV pneumonia in bone marrow transplant recipients. Combination ribavirin and pegylated IFN therapy is licensed for the treatment of hepatitis C.

3. Resistance

Emergence of viruses resistant to ribavirin has not been documented.

4. Adverse effects

Adverse effects attributable to aerosol therapy with ribavirin of infants with RSV include bronchospasm, pneumothorax in ventilated patients, apnea, cardiac arrest, hypotension, and concomitant digitalis toxicity. Pulmonary function test changes after ribavirin therapy in adults with chronic obstructive pulmonary disease have been noted. Reticulocytosis, rash, and conjunctivitis have been associated with the use of ribavirin aerosol. When given orally or intravenously, transient elevations of serum bilirubin and the occurrence of mild anemia have been reported. Ribavirin has been found to be teratogenic and mutagenic in preclinical testings. This drug is therefore contraindicated in women who are or may become pregnant during exposure to the drug.

Concern has been expressed about the risk to persons in the room of infants being treated with ribavirin aerosol, particularly females of childbearing age. Although this

risk seems to be minimal with limited exposure, awareness and caution are warranted. Furthermore, the use of a "drug salvage" hood is mandatory.

5. Hepatitis C

With interferon- α , ribavirin is approved for combination therapy of chronic hepatitis C (see Section III.A).

III. HEPATITIS AND PAPILOMAVIRUS

A. Interferons

1. Chemistry, mechanism of action, and antiviral activity

Interferons (IFNs) are glycoprotein cytokines (intracellular messengers) with a complex array of immunomodulating, antineoplastic, and antiviral properties. Interferons are currently classified as α , β , or γ , the natural sources of which, in general, are leukocytes, fibroblasts, and lymphocytes, respectively. Each type of IFN can be produced via recombinant DNA technology. Binding of IFN to the intact cell membrane is the first step in establishing an antiviral effect. Interferon binds to specific cell surface receptors; IFN- γ appears to have a different receptor from those of IFN- α and - β which may explain the purported synergistic antiviral and antitumor effects sometimes observed when IFN- γ is given with either of the other two IFN species.

A prevalent view of IFN action is that, following binding, there is synthesis of new cellular RNAs and proteins, particularly protein kinase R, which mediate the antiviral effect. Chromosome 21 is required for this antiviral state in humans, no matter which species of IFN is employed. At least three of the newly synthesized proteins in IFN-treated cells appear to be associated with the development of an antiviral state: (i) 2'5'-oligoadenylate synthetase, (ii) a protein kinase, and (iii) an endonuclease. The antiviral state is not fully expressed until these primed cells are infected with virus.

Interferon must be administered intramuscularly or subcutaneously (including into a lesion such as a wart). Plasma levels are dose dependent, peaking 4–8 h after intramuscular administration and returning to baseline between 18 and 36 h. There appears to be some variability in absorption between each of the three classes of IFN and, importantly, resultant plasma levels. Leukocyte and IFN- α appear to have elimination $t_{1/2}$ values of 2–4 h. Interferon is inactivated by various organs of the body in an as yet undefined method.

2. Clinical indications

a. *Condyloma acuminatum*

Several large, controlled trials have demonstrated the clinical benefit of IFN- α therapy of condyloma acuminatum which was refractory to cytotoxic therapies. Administration of 1.0×10^6 International Units (IU) of recombinant IFN- α led to significant benefit as evidenced by enhancing clearing of treated lesions (36 vs 17% placebo recipients) and by reduction in mean wart area (40% reduction vs 46% increase). In other well-controlled studies, either a similar rate (46%) or higher rates (62%) of clearance were reported. Notably, clearing responses of placebo recipients averaged 21 or 22%.

b. Hepatitis B

Hepatitis B DNA polymerase level, a marker of replication, is reduced with IFN therapy. Treatment with IFN- α in chronic hepatitis B has subsequently been investigated in several large, randomized, controlled trials. Clearance serum HBeAg and hepatitis B virus (HBV)-DNA polymerase occurs with treatment (30–40%).

c. Hepatitis C

The activity of IFN as a treatment of hepatitis C has undergone extensive evaluation. Interferon dosages have ranged from 1×10^6 to 10×10^6 IU three times weekly for 1–18 months. Of the placebo controls, only 2.6% normalized serum alanine amino transferase (ALT). In contrast, treatment led to serum ALT normalization in 33–45% of patients. Unfortunately, 50–80% of patients relapsed. Recently, IFN- α has been administered with ribavirin. Concomitant therapy for 40 weeks resulted in sustained responses in more than 60% of patients.

3. Resistance

Resistance to administered interferon has not been documented although neutralizing antibodies to recombinant interferons have been reported. The clinical importance of this latter observation is unknown.

4. Adverse effects

Side effects are frequent with IFN administration and are usually dose limiting. Influenza-like symptoms (i.e., fever, chills, headache, and malaise) commonly occur, but these symptoms usually become less severe with repeated treatments. At doses used in the treatment of condyloma acuminatum, these side effects rarely cause termination of treatment. For local

treatment (intralesional administration), pain at the injection site does not differ significantly from that for placebo-treated patients and is short-lived. Leukopenia is the most common hematologic abnormality, occurring in up to 26% of treated patients. Leukopenia is usually modest, not clinically relevant, and reversible upon discontinuation of therapy. Increased alanine aminotransferase levels may also occur as well as nausea, vomiting, and diarrhea.

At higher doses of IFN, neurotoxicity is encountered, as manifested by personality changes, confusion, loss of attention, disorientation, and paranoid ideation. Early studies with IFN- γ show similar side effects as those of treatment with and IFN- α and - β but with the additional side effects of dose-limiting hypotension and a marked increase in triglyceride levels.

B. Adefovir dipivoxil

1. Chemistry, mechanism of action, and antiviral activity

Adefovir dipivoxil, bis-pivaloyloxymethyl-9-(2-phosphonyl-methoxyethyl)adenine, is the orally bioavailable prodrug of adefovir.

2. Clinical indications

Adefovir has activity against both herpes and hepadnavirus. It is in the nucleotide class of medications. Treatment of chronic hepatitis B at 10 mg daily significantly decreases HBV DNA polymerase (3.56 logs compared with 0.55 logs in placebo recipients), improves hepatic histopathology scores, and induces loss of HBeAg.

3. Resistance

Mutations within the HBV DNA polymerase which confer resistance to adefovir have not been identified in clinical trials. HBV isolates resistant to lamivudine or hepatitis B hyperimmune globulin retain susceptibility to adefovir.

4. Adverse events

Severe acute exacerbation of hepatitis has been reported who have discontinued anti-HBV therapy. Lactic acidosis and severe hepatomegaly with steatosis have also been reported.

C. Entecavir

[1S-(1 α ,3 α ,4 β)]-2-amino-1,9-dihydro-9[4-hydroxymethyl-2-methylenecyclopentyl]-6H-purin-6-one, is a nucleoside analog that is orally bioavailable for the

treatment of chronic hepatitis B. Phase III trials are in progress.

IV. PROSPECTS FOR ENTEROVIRAL THERAPIES

Pleconaril, a compound with activity against many rhinoviruses and enteroviruses, is the first compound for which data exist to define anti-viral drug interaction with a virion at the atomic level. This compound is one of a class of compounds which resembles arildone, a drug known to inhibit uncoating of poliovirus. X-ray diffraction studies of bound to rhinovirus 14 show that the compound adheres tightly to a hydrophobic pocket formed by VP1, one of the structural proteins of rhinovirus 14. These hydrophobic pockets were found in the VP1 proteins of poliovirus and meningovirus and may be common to all picornaviruses. These compounds may lock into the conformation of the VP1 so that the virus cannot disassemble.

Pleconaril is under investigation for chronic enterovirus infections of the CNS in the immune deficient patients. It was shown to have an inadequate therapeutic index for therapy of rhinovirus cold.

V. ANTIRETROVIRAL AGENTS

A. Reverse transcriptase inhibitors

1. Zidovudine

a. Chemistry, mechanism of action, and antiviral activity

Zidovudine (3'-azido-2',3'-dideoxythymidine; azidothymidine and Retrovir) is a pyrimidine analog with an azido group substituting for the 3' hydroxyl group on the ribose ring. The drug is initially phosphorylated by cellular TK and then to its diphosphate by cellular thymidylate kinase. The triphosphate derivative competitively inhibits HIV reverse transcriptase and also functions as a chain terminator. Zidovudine inhibits HIV-1 at concentrations of approximately 0.013 $\mu\text{g}/\text{ml}$.

In addition, it inhibits a variety of other retroviruses. Synergy has been demonstrated against HIV-1 when zidovudine is combined with didanosine, zalcitabine, lamivudine, nevirapine, delavirdine, saquinavir, indinavir, ritonavir, and other compounds. It was the first drug to be licensed for the treatment of HIV infection and still is used in combination with other drugs as initial therapy for some patients.

Zidovudine is available in capsule, syrup, and intravenous formulations. Oral bioavailability is approximately 65%. Peak plasma levels are achieved approximately 0.5–1.5 h after treatment. Zidovudine is extensively distributed, with a steady-state volume of distribution of approximately 1.6 liters/kg. The drug penetrates cerebrospinal fluid, saliva, semen, and breast milk, and it crosses the placenta. The drug is predominately metabolized by the liver through the enzyme uridine diphosphoglucuronosyltransferase to its major inactive metabolite 3'-azido-3'-deoxy-5'-O-B-D-glucopyranuronosylthymidine. The elimination $t_{1/2}$ is approximately 1 h; however, it is extended in individuals who have altered hepatic function.

b. Clinical applications

Zidovudine was the first approved antiretroviral agent, and as a consequence, has been the most widely used antiretroviral drug in clinical practice. In monotherapy studies, zidovudine improves survival and decreases the incidence of opportunistic infections in patients with advanced HIV disease. Importantly, zidovudine decreased the incidence of transmission of HIV infection from pregnant women to their fetuses. However, its usefulness as monotherapy has been outlived.

Recently, zidovudine has been incorporated into multidrug regimens, including combinations with didanosine or zalcitabine which demonstrate a delay in disease progression and improved survival compared to zidovudine monotherapy; zidovudine plus didanosine and zidovudine plus lamivudine have also been shown to improve both outcome and important markers of disease, including CD4 counts and plasma HIV RNA levels.

Currently, three-drug combinations include the use of zidovudine with other reverse transcriptase inhibitors and nonnucleoside reverse transcriptase inhibitors and protease inhibitors. Triple-drug combinations offer enhanced therapeutic benefits, particularly as noted by survival and restoration of normal immune function.

c. Resistance

Zidovudine resistance occurs rapidly after the onset of therapy. Numerous sites of resistance have been

identified, with the degree of resistance being proportional to the number of mutations. The development of resistant HIV strains correlates with disease progression. The utilization of combination drug therapies delays the onset of resistance.

d. Adverse events

The predominant adverse effect of zidovudine is myelosuppression, as evidenced by neutropenia and anemia, occurring in 16 and 24% of patients, respectively. Zidovudine has been associated with skeletal and cardiac muscle toxicity, including polymyositis. Nausea, headache, malaise, insomnia, and fatigue are common side effects.

2. Didanosine

a. Chemistry, mechanism of action, and antiviral activity

Didanosine (2',3'-dideoxyinosine; ddl and Videx) is a purine nucleoside with inhibitory activity against both HIV-1 and HIV-2. Didanosine is activated by intracellular phosphorylation. The conversion of 2',3'-dideoxyinosine-5'-monophosphate to its triphosphate derivative is more complicated than that with other nucleoside analogs because it requires additional enzymes, including a 5' nucleotidase and subsequently, adenylosuccinate synthetase and adenylosuccinate lyase. The triphosphate metabolite is a competitive inhibitor of HIV reverse transcriptase and is also a chain terminator. The spectrum of activity of didanosine is enhanced by synergism with zidovudine and stavudine as well as the protease inhibitors.

Didanosine is available in an oral formulation; however, it is acid labile and has poor solubility. A buffered tablet results in 20–25% bioavailability. A 300-mg oral dose achieves peak plasma concentrations of 0.5–2.6 $\mu\text{g/ml}$ with a $t_{1/2}$ of approximately 1.5 h. Drug is metabolized to hypoxanthine and is cleared primarily by the kidney.

b. Clinical indications

Didanosine is used in combination with other nucleoside analogs and protease inhibitors. In combination

with zidovudine, improvement in both clinical outcome and immunologic markers of disease has been reported (CD4 lymphocyte counts).

c. Resistance

As with zidovudine, mutations and reverse transcriptase appear promptly after administration of didanosine therapy, resulting in a 3- to 10-fold decrease in susceptibility to therapy.

d. Adverse effects

The most significant adverse effect associated with didanosine therapy is the development of peripheral neuropathy (30%) and pancreatitis (10%). Adverse effects of note include diarrhea (likely attributed to the phosphate buffer), headache, rash, nausea, vomiting, and hepatotoxicity. Myelosuppression is not a component of toxicity associated with didanosine administration.

3. Zalcitabine

a. Chemistry, mechanism of action, and antiviral activity

Zalcitabine (2',3'-dideoxycytidine; ddC and Hivid) is a pyrimidine analog which is activated by cellular enzymes to its triphosphate derivative. The enzymes responsible for activation of zalcitabine are cell cycle independent, and therefore this offers a theoretical advantage for nondividing cells, specifically dendritic and monocyte/macrophage cells. Zalcitabine inhibits both HIV-1 and HIV-2 at concentrations of approximately 0.03 μM . Synergy has been described between zidovudine and zalcitabine as well as with saquinavir.

The oral bioavailability following zalcitabine administration is more than 80%. The peak plasma concentrations following an oral dose of 0.03 mg/kg range from 0.1 to 0.2 μM , and the $t_{1/2}$ is short (approximately 20 min). The drug is cleared mainly by the kidney, and therefore, in the presence of renal insufficiency a prolonged plasma $t_{1/2}$ is documented.

b. Clinical indications

Zalcitabine is used in combination with other reverse transcriptase and protease inhibitors. As with other nucleoside combinations, zidovudine and zalcitabine do not benefit patients to the same extent as combinations of zidovudine and didanosine. Currently, it is used as part of a two- or three-drug regimen in combination with zidovudine and saquinavir.

c. Resistance

Zalcitabine-resistant HIV-1 variance has been documented both *in vitro* and *in vivo*.

d. Adverse effects

Peripheral neuropathy is the major toxicity associated with zalcitabine administration, occurring in approximately 35% of individuals. Pancreatitis can occur but does so infrequently. Thrombocytopenia and neutropenia are uncommon (5 and 10%, respectively). Other zalcitabine-related side effects include nausea, vomiting, headache, hepatotoxicity, and cardiomyopathy.

4. Stavudine

a. Chemistry, mechanism of action, and antiviral activity

Stavudine (2',3'-didehydro, 3'-deoxythymidine; d4T and Zerit) is a thymidine analog with significant activity against HIV-1, having inhibitory concentrations which range from 0.01 to 4.1 μM . Its mechanism of action is similar to that of zidovudine. It is either additive or synergistic *in vitro* with other combinations of both nucleoside and nonnucleoside reverse-transcriptase inhibitors.

The oral bioavailability of stavudine is more than 85%. Peak plasma concentrations of approximately 1.2 $\mu\text{g/ml}$ are reached within 1 h of dosing at 0.67 mg/kg per dose. The drug penetrates CSF and breast milk. The drug is excreted by the kidney unchanged and, in part, by renal tubular secretion.

b. Clinical indications

Stavudine has been studied both as monotherapy and in combination with other antiretroviral drugs. It is gaining increasing use as front-line therapy for HIV infection. Stavudine's clinical benefit is superior to that of zidovudine, particularly as it relates to

increasing CD4 cell counts, slowing progression to AIDS or mortality.

c. Resistance

The development of resistance on serial passage in the laboratory can be achieved. Cross-resistance with didanosine and zalcitabine has been identified by specific mutations for stavudine. The development of resistance in clinical trials has not been identified.

d. Adverse effects

The principal adverse effect of stavudine therapy is the development of peripheral neuropathy. The development of this complication is related to both dose and duration of therapy. Neuropathy tends to appear after 3 months of therapy and resolves slowly with medication discontinuation. Other side effects are uncommon.

5. Lamivudine

a. Chemistry, mechanism of action, and antiviral activity

Lamivudine is the (–) enantiomer of a cytidine analog, with sulfur substituted for the 3' carbon atom in the furanose ring [(–) 2',3'-dideoxy, 3'-thiacytidine; 3TC, Epivir]. It has significant activity *in vitro* against both HIV-1 and HIV-2 as well as HBV. Lamivudine is phosphorylated to the triphosphate metabolite by cellular kinases. The triphosphate derivative is a competitive inhibitor of the viral reverse transcriptase.

Lamivudine's oral bioavailability in adults is in excess of 80% for doses between 0.25 and 8.0 mg/kg. Peak serum concentrations of 1.5 μg/ml are achieved in 1–1.5 h and the plasma $t_{1/2}$ is approximately 2–4 h. The drug is cleared by the kidney unchanged by both glomerular filtration and tubular excretion.

b. Clinical indications

Lamivudine is used in combination with other reverse transcriptase inhibitors and protease inhibitors. In combination with zidovudine, enhanced CD4 responses and suppression of HIV RNA levels occur to a greater extent than with zidovudine monotherapy. The combination of zidovudine and lamivudine is without significant adverse event. Because of this degree of tolerability, it is widely used in clinical practice.

In addition, lamivudine is licensed for the treatment of chronic hepatitis B. However, resistance appears soon after administration in many patients.

c. Resistance

With clinical therapy, resistance to lamivudine monotherapy develops rapidly. In large part, resistance is mediated by amino acid change at codon 184, resulting in a 100- to 1000-fold decrease in susceptibility. The 184 mutation site, which is of importance, also occurs with didanosine and zalcitabine and appears to increase sensitivity to zidovudine, providing a logical basis for its combination with this agent.

d. Adverse effects

Lamivudine has an extremely favorable toxicity profile. This may largely be attributed to the low affinity of lamivudine for DNA polymerase. At the highest doses of 20 mg/kg/day, neutropenia is encountered but at a low frequency. In pediatric studies, pancreatitis and peripheral neuropathies have been reported.

6. Abacavir

1. Chemistry, mechanism of action, and antiviral activity

Abacavir is a carbocyclic synthetic nucleoside analogue. Intracellularly, abacavir is phosphorylated by cellular enzymes to its active metabolite, carbovir triphosphate, which is an analogue of deoxyguanosine-5'-TP. Carbovir TP then inhibits the activity of HIV reverse transcriptase both by competing with the natural substrate dGTP and by its incorporation into viral DNA. The lack of a 3'-OH group in the incorporated nucleoside analogue prevents the formation of the 5' to 3' phosphodiester linkage essential for DNA chain elongation, producing chain termination.

2. Clinical indications

Abacavir often is used in combination with lamivudine and zidovudine, as well as with either a non-nucleoside reverse transcriptase inhibitor or protease inhibitor. It is licensed for the treatment of HIV infections of humans. The proposed dosage is 300 mg daily.

3. Resistance

Abacavir resistance is conferred by mutations in the HIV reverse transcriptase gene that resulted in amino acid substitutions at positions K65R, L74V, Y115F, and M184V. M184V and L74V are the most frequently observed mutations among clinical isolates. Multiple reverse transcriptase mutations conferring abacavir resistance exhibit cross-resistance to lamivudine, didanosine, and zalcitabine *in vitro*.

4. Adverse events

Adverse reactions associated with abacavir therapy include nausea, headache, stomach pain, diarrhea, insomnia, rash, fever, and dizziness. Importantly, fatal hypersensitivity reactions have been associated with abacavir use.

B. Non-nucleoside reverse transcriptase inhibitors

1. Nevirapine

a. Chemistry, mechanism of action, and antiviral activity

Nevirapine (11-cyclopropyl-5,11-dihydro-4-methyl-6H-dipyrido[3,2-b:2',3'-e]; [1,4]diazepin-6-one and Viramune) is a reverse transcriptase inhibitor of HIV-1. Nevirapine is rapidly absorbed with a bioavailability of approximately 65%. Peak serum concentration is achieved approximately 4 h after a 400-mg oral dose of 3.4 $\mu\text{g}/\text{ml}$. Nevirapine is metabolized by liver microsomes to hydroxymethyl-nevirapine. *In vitro*, synergy has been demonstrated when administered with nucleoside reverse transcriptase inhibitors.

b. Clinical indications

Nevirapine monotherapy is associated with a non-sustained antiviral effects at a dosage of 200 mg/day. Concomitant with this minimal effect is the rapid emergence of resistant virus, such that by 8 weeks all patients had evidence of viral resistance. Thus, drug can only be administered in combination with other antiretroviral agents. In combination with nucleoside reverse-transcriptase inhibitors, there is evidence of reduction in viral HIV RNA load as well as increasing CD4 counts.

c. Adverse effects

The most common adverse effects include the development of a nonpruritic rash in as many as 50% of patients who received 400 mg/day. In addition, fever, myalgias, headache, nausea, vomiting, fatigue, and diarrhea have also been associated with administration of drug.

d. Resistance

Nevirapine resistance has been identified according to its binding site on viral polymerase. Specifically, two sets of amino acid residues (100–110 and 180–190) represent sites at which resistant mutations have occurred. Nevirapine monotherapy is associated with resistance, most frequently appearing at codon 181. Because of the rapid appearance of resistance, nevirapine must be administered with other antiretroviral agents.

2. Delavirdine

a. Chemistry, mechanism of action, and antiviral activity

Delavirdine (1-[5-methanesulfonamido-1H-indol-2-yl-carbonyl]-4-[3-(1-methylethylamino)pyridinyl]piperazine; Rescriptor) is a second-generation bis(heteroaryl) piperazine licensed for the treatment of HIV infection. It is absorbed rapidly when given orally to >60%. Delavirdine is metabolized by the liver with an elimination $t_{1/2}$ of approximately 1.4 h. It has an inhibitory concentration against

HIV-1 of approximately $0.25 \mu\text{M}$. Inhibitory concentrations for human DNA polymerases are significantly higher.

b. Clinical indications

Reductions in plasma HIV RNA of more than 90% have been documented when delavirdine is administered such that trough levels exceed $50 \mu\text{M}$. However, there is a rapid return to baseline over 8 weeks as resistance develops. As a consequence, delavirdine must be administered with either zidovudine or didanosine to have a more protracted effect.

c. Adverse effects

Delavirdine administration is associated with a maculopapular rash. Other side effects are less common.

d. Resistance

Delavirdine resistance can be generated rapidly both *in vitro* and *in vivo* with the codon change identified at 236, resulting in an increase and susceptibility to $>60 \mu\text{M}$. Delavirdine resistance can also occur at codons 181 and 188, as noted for nevirapine administration.

3. Efavirenz

a. Chemistry, mechanism of action, and antiviral activity

Efavirenz Sustiva [(*S*)-6-chloro-4-(cyclopropylethynyl)-1,4-dihydro-4-(trifluoromethyl)-2*H*-3,1-benzoxazin-2-one; Sustiva and DMP266] is a nonnucleoside reverse-transcriptase inhibitor which can be administered once daily. Activity is mediated predominately by noncompetitive inhibition of HIV-1 reverse transcriptase. HIV-2 reverse transcriptase in human cellular DNA polymerases α , β , γ , and δ are not inhibited by efavirenz. The 90–95% inhibitory concentration of efavirenz is approximately 1.7–25 nM. In combination with other anti-HIV agents, particularly zidovudine, didanosine, and indinaver, synergy is demonstrated.

b. Clinical indications

Efavirenz is employed in combination with other anti-retroviral agents indicated in the treatment of HIV-1 infection. Efficacy has been documented in the demonstration of plasma HIV negativity (<400 HIV RNA copies/ml) in approximately 80% of patients. Combination therapy has resulted in a 150-fold or greater decrease in HIV-1 RNA levels. Importantly, data have shown efficacy in children for both virologic and immunologic end points.

c. Adverse effects

The most common adverse events are skin rash (25%), which is associated with blistering, moist desquamation, or ulceration (1%). In addition, delusions and inappropriate behavior have been reported in 1 or 2 patients per 1000.

d. Resistance

As with other non-nucleoside reverse-transcriptase inhibitors, resistance appears rapidly and is mediated by similar enzymes.

4. Future Prospect

Capravirine

Capravirine is a non-nucleoside reverse transcriptase inhibitor currently under investigation. Need more It has potent *in vitro* activity against HIV variants with RT substitutions, including K103N that confer broad cross resistance to the other drugs in this class.

C. Protease inhibitors

1. Saquinavir

a. Chemistry, mechanism of action, and antiviral activity

Saquinavir (*cis*-*N*-*tert*-butyl-decahydro-2[2(*R*)-hydroxy-4-phenyl-3-(*S*)-([*N*-(2-quinolylcarbonyl)-*L*-asparginyl] amino butyl)-4*aS*, 8*aS*]-isoquinoline-3[*S*]-carboxamide methanesulfonate; Invirase) is a hydroxyethylamine-derived peptidomimetic HIV protease inhibitor.

Saquinavir inhibits HIV-1 and HIV-2 at concentrations at 10 nM and is synergistic with other nucleoside analogs as well as selected protease inhibitors.

Oral bioavailability is approximately 30% with extensive hepatic metabolism. Peak plasma concentrations of 35 mg/ μ l are obtained following a 600-mg dose.

b. Clinical indications

The clinical efficacy of saquinavir is limited by poor oral bioavailability, but improved formulation (soft-gel capsule) will likely enhance efficacy. Currently, it is used in combination therapy with other nucleoside analogs, particularly zidovudine, lamivudine, zalcitabine, and stavudine.

c. Adverse effects

Adverse effects are minimal, with no dose-limiting toxicities. Abdominal discomfort, including diarrhea, nausea, and photo sensitization has been reported infrequently.

d. Resistance

Resistance to saquinavir develops rapidly when it is administered as monotherapy. By 1 year, 45% of patients develop resistance at codon sites 90 and 48, resulting in, an approximately 30-fold decrease in susceptibility.

2. Indinavir

a. Chemistry, mechanism of action, and antiviral activity

{*N*-[2(*R*)-hydroxy-1(*S*)-indanyl]-5-[2(*S*)-(1,1-dimethylethylaminocarbonyl)-4-(pyridin-3-yl) methylpiperazin + + + -1-yl]-4[*s*]-hydroxy-2[2]-phenylmethyl entanamide; Crixivan} is a peptidomimetic HIV-1 and HIV-2 protease inhibitor. At concentrations of 100 nM, indinavir inhibits 90% of HIV isolates. Indinavir is rapidly absorbed with a bioavailability of 60% and achieves peak plasma concentrations of 12 μ M after an 800-mg oral dose.

b. Clinical indications

Indinavir has been established as effective therapy for the treatment of HIV infection, particularly in combination with nucleoside analogs. At a dose of 800 mg per 8 h, 80% of patients experience at least a 100-fold reduction in HIV-RNA levels, and in 50% of patients there is up to a 2 log reduction. In approximately 30% of patients plasma HIV RNA levels are reduced below 500 copies/ml, with an associated increase in CD4 cell counts over baseline. In combination with zidovudine and lamivudine, a >2 log decrease in plasma RNA levels can be achieved for a majority of patients (more than 80%).

c. Adverse effects

Although indinavir is well tolerated, commonly encountered adverse effects include indirect hyperbilirubinemia (10%) and nephrolithiasis (5%).

d. Resistance

Indinavir resistance develops rapidly with monotherapy and occurs at multiple sites. The extent of resistance is directly related to the number of codon changes in the HIV protease gene. Codon 82 is a common mutation in indinavir-resistant HIV isolates.

3. Ritonavir

a. Chemistry, mechanism of action, and antiviral activity

Ritonavir (10-hydroxy-2-methyl-5-[1-methylethyl]-1[2-(1-methylethyl)-4-thiazolyl]-3,6,dioxo-8,11-bis[phenylmethyl]-2,4,7,12-tetra azatridecan-13-oic-acid, 5-thiazolylmethyl ester, [5*S*-(5*R*, 8*R*, 10*R*, 11*R*)]; Norvir) is a symmetric HIV protease inhibitor which has exquisite activity *in vitro* against HIV-1 laboratory strains (0.02–0.15 μ M). It is synergistic when administered with nucleoside analogs.

Oral bioavailability is approximately 80%, with peak plasma levels of approximately 1.8 μ M after 400 mg administered every 12 h. The plasma half-life is approximately 3 h.

b. Clinical indications

Ritonavir is used for treatment of HIV infection in combination with nucleoside analogs. As monotherapy, a 10- to 100-fold decrease in plasma HIV RNA is achieved with a concomitant increase in CD4

cell counts of approximately 100 cells/mm³. Combination therapy results in a more significant decrease in HIV RNA plasma levels.

c. Adverse effects

Adverse effects include nausea, diarrhea, and headache, but all occur at a low frequency.

d. Resistance

Resistance to ritonavir resembles that to indinavir. Mutations at codon 82 are the most common.

4. Nelfinavir

a. Chemistry, mechanism of action, and antiviral activity

Nelfinavir [3*S*-(3*R*, 4*aR*, 8*aR*, 22'*S*, 3'*S*)]-2-[2'-hydroxy-3'-phenylthiomethyl-4'-aza-5'-oxo-5'-(2'-methyl-3'-hydroxyphenyl)pentyl]-decahydroisoquinoline-3-*N*-(tert-butyl-carboxamide methanesulfonic acid salt) is another peptidomimetic HIV protease inhibitor. Inhibitory concentrations of HIV-1 are in the range of 20–50 nM. Nelfinavir is orally bioavailable at approximately 40%, achieving peak plasma concentrations of 2 or 3 mg following a 800-mg dose every 24 h. The drug is metabolized by hepatic microsomes.

b. Clinical indications

Nelfinavir is utilized in combination with nucleoside analogs. Monotherapy will achieve significant decreases in HIV RNA plasma levels up to 100-fold. Currently, the drug is used in combination with nucleoside analogs, particularly zidovudine, lamivudine, or stavudine, which results in 100- to 1000-fold reductions of HIV plasma RNA levels.

c. Adverse effects

Nelfinavir is well tolerated, with mild gastrointestinal complication reported.

d. Resistance

Cross-resistance to other protease inhibitors, particularly saquinavir, indinavir, or ritonavir, is not common. The most frequently demonstrated site of mutation is at codon 30.

5. Amprenavir

a. Chemistry, mechanism of action, and antiviral activity

Amprenavir is a hydroxyethylamine sulfonamide peptidomimetic with a structure identified as (3*S*)-tetrahydro-3-furyl *N*-(1*S*,2*R*)-3-(4-amino-*N*-isobutylbenzenesulfonamido)-1-benzyl-2-hydroxypropyl carbamate. It is active at a concentration of 10–20 nM. The oral bioavailability is >70%, and peak plasma concentrations of 6.2–10 µg/ml are achieved after dosages of 600–1200 mg. The plasma half-life is 7–10 h. Cerebrospinal fluid concentrations are significant.

Amprenavir acts by binding to the active site of HIV-1 protease, preventing the processing of viral gag and gag-pol polyprotein precursors and resulting in the formation of immature non-infectious viral particles. *In vitro*, amprenavir has synergistic anti-HIV-1 activity in combination with abacavir, zidovudine, didanosine, or saquinavir, and additive anti-HIV-1 activity in combination with indinavir, nelfinavir, and ritonavir.

2. Clinical indications

Amprenavir is licensed for the treatment of HIV infections. The recommended dosage for adults is 1200 mg twice daily.

3. Adverse effects

The most serious adverse effect is a rash. Other side effects include nausea, vomiting, diarrhea, abdominal pain, and perioral paresthesias.

4. Resistance

Resistance to amprenavir is conferred by amino acid substitutions primarily at positions M46I/L, I47V, I50V, I54L/V, and I84V, as well as mutations in the viral protease p1/p6 cleavage site. Cross-resistance between amprenavir and the other protease inhibitors is possible.

6. Lopinavir/Ritonavir

Lopinavir/ritonavir combination (marketed as Kaletra) interferes with processing of viral polyprotein precursors, resulting in non-infectious progeny virions. The addition of ritonavir enhances the concentrations of lopinavir that which can be achieved following oral administration. It is given in combination with nucleoside and/or non-nucleoside reverse transcriptase inhibitors. Side effects of lopinavir/ritonavir include diarrhea, nausea, abdominal pain, and headache.

As lopinavir/ritonavir is a new addition to the protease inhibitors, a complete understanding of resistance profiles will await its widespread utilization.

D. Nucleotide Analogues

Viread; Tenofovir (tenofovir disoproxil fumarate)

Tenofovir or disoproxil fumarate salt is an acyclic nucleoside phosphonate diester analog of adenosine monophosphate with an *in vitro* the 50% inhibitor concentration for HIV is 0.04–8.5 μ mol. After diester hydrolysis, tenofovir is phosphorylated to the DP that then inhibits HIV reverse transcriptase by competing with the natural substrate deoxyadenosine 5-TP and, after incorporation into DNA, by DNA chain termination. Tenofovir DP is a weak inhibitor of mammalian DNA polymerases alpha, beta and mitochondrial DNA polymerase gamma. Additive or synergic anti-HIV activity with nucleoside analog, non-nucleoside analog and protease inhibitors has been demonstrated *in vitro*. Side effects include lactic acidosis, hepatomegaly with steatosis, and diarrhea.

Resistance is uncommon and occurs at codon 65.

E. HIV Fusion Inhibitors

Fuseon; Enfuvirtide

The recent licensure of a fusion inhibitor introduces a new class of antiviral compounds for the treatment of HTV. T-20 is an inhibitor of fusion of HIV-1 with CD4 cells that consists of a 36 amino acid synthetic peptide with the N-terminus acetylated and the

C-terminus is a carboxamide. Medication is administered subcutaneously.

VI. SUMMARY

It is anticipated that many new compounds will be licensed for the treatment of viral disease because many are currently under development.

Archaea

Paul Blum and Vidula Dixit

George Beadle Center for Genetics, University of Nebraska-Lincoln

GLOSSARY

Archaea One of three domains of life. From the Greek *archaios* (ancient, primitive). Prokaryotic cells; membrane lipids predominantly isoprenoid glycerol diethers or diglycerols tetraethers. Formerly called archaeobacteria.

Bacteria One of three domains of life. From the Greek *bacterion* (staff, rod). Prokaryotic cells; membrane lipids predominantly diacyl glycerol diesters. Formerly called eubacteria.

Crenarchaeota One of two kingdoms of organisms of the domain Archaea. From the Greek *crene-* (spring, fountain) for the resemblance of these organisms to the ancestor of the Archaea, and *archaios* (ancient). Include sulfur-metabolizing, extreme thermophiles.

Eukarya One of three domains of life. From the Greek *eu-* (good, true) and *karion*, (nut; refers to the nucleus). Eukaryotic cells; cell membrane lipids predominantly glycerol fatty acyl diesters.

Euryarchaeota One of two kingdoms within the domain Archaea. From the Greek *eurys-* (broad, wide), for the relatively broad patterns of metabolism of these organisms, and *archaios* (ancient). Include halophiles, methanogens, and some anaerobic, sulfur-metabolizing, extreme thermophiles.

halophiles From the Greek *halos-* (salt) and *philos* (loving). Includes organisms that grow optimally at high salt concentrations.

hyperthermophiles From the Greek *hyper-* (over), *therme-* (heat), and *philos* (loving). Includes organisms that grow optimally at temperatures warmer than 80°C.

mesophiles From the Greek *mesos-* (middle) and *philos* (loving). Includes organisms that grow optimally at temperatures between 20 and 50°C.

methanogens Strictly anaerobic Archaea that produce (Greek *gen*, to produce) methane.

psychrophiles From the Greek *psychros-* (cold) and *philos* (loving). Includes organisms that grow optimally at temperatures between 0 and 20°C.

thermophiles From the Greek *therme-* (heat) and *philos* (loving). Includes organisms that grow optimally at temperatures between 50 and 80°C.

I. INTRODUCTION

In an effort to accommodate molecular signatures evident in ribosomal small subunit RNAs, Woese and Fox (1977) proposed that prokaryotes are not a monophyletic group (single root). Instead, they argued for two distinct evolutionary lineages of organisms represented by the Bacteria and those now called Archaea (Fig. 7.1). Archaea, Bacteria and Eukarya are placed in separate taxonomic groups called Domains. The distinction between Archaea and Bacteria has since received impressive support from many sources.

FIGURE 7.1 Universal (distance) phylogenetic tree based on ribosomal small subunit RNA sequences.

Perhaps the most compelling data comes from whole genome sequencing studies which reveal extensive gene and protein sequence conservation between members of the Archaea but not Bacteria. Comparative genomics also suggest that Archaea are a distinct group and share a common origin with Eukarya. This is further supported by the finding that Archaea employ a broad range of eukaryotic-like genes for conducting subcellular processes including the synthesis and processing of DNA, RNA, and protein (Blum, 2001). In contrast, Archaea use bacterial-like mechanisms for much of central metabolism including key biosynthetic (anabolic) and degradative (catabolic) pathways.

Archaea derived from extreme environments are studied intensively leading to the incorrect interpretation that all Archaea are extremophiles. Since extreme environments comprise only a small portion of inhabitable earth, Archaea are often thought to comprise only a small proportion of total prokaryotes. In contrast to this notion, studies on marine prokaryotic abundance indicate that global oceans harbor approximately equal numbers of archaeal and bacterial cells (Karner *et al.*, 2001). The major fraction of these Archaea are assigned to the subdivision called Crenarchaeota and these represent one of the ocean's single most abundant cell types. Archaea are also evident in soil and

fresh water, and are associated with plant roots. It may be that Archaea are as abundant a life form as Bacteria.

Archaea are readily distinguished from Bacteria by several universal and unique chemical features. In contrast, the ecology and physiology of Archaea often overlaps that of Bacteria with the notable absence of differentiated cell forms or developmental cycles. Investigations of archaeal genomics and their molecular biology, however, reveals the true magnitude of the similarities between Archaea and Eukarya and differences from Bacteria. Perhaps this latter finding explains the utter lack of pathogenic Archaea despite the occurrence of host-adapted species such as the methanogens.

II. CELL STRUCTURE OF THE ARCHAEA

Archaea, like Bacteria, are prokaryotes (Table 7.1). They lack membrane-bound organelles such as a nucleus, or mitochondria, and are devoid of a cytoskeleton. Their chromosomal DNA is typically a single circular molecule and their ribosomes are of the 70S type. Their cell membranes and surface layers

TABLE 7.1 Major features distinguishing archaea and bacteria

Characteristic	Archaea ^a	Bacteria
Cell envelope		
(a) Wall	Mostly S-layer	Peptidoglycan
Membrane		
(a) Chirality of glycerol	L-glycerol	D-glycerol
(b) Hydrocarbon glycerol linkage	Ether-linkage	Ester-linkages
(c) Side-chains	Isoprene	Fatty acids
(d) Side-chain branching	Highly branched	Linear
Bacterial antibiotic sensitivity		
(a) Cell wall inhibitors	No	Yes
(b) Protein synthesis inhibitors	No ^a	Yes
(c) Transcription inhibitors	No	Yes

^aSome methanogenic Archaea are sensitive to puromycin and chloramphenicol.

(envelope) are structurally and chemically distinct from those of Bacteria.

Archaeal cell envelope. Bacterial envelopes usually comprise a peptidoglycan wall with a single lipid bilayer internal to the wall (gram-positive Bacteria) or two lipid bilayers one internal and the other external to the wall (gram-negative Bacteria). In contrast, Archaea have neither peptidoglycan nor a wall. Instead the most common outer layer of their envelope consists of a paracrystalline S-layer, composed of noncovalently linked hexagonally or tetragonally arranged protein or glycoprotein subunits. Methanogens show particular diversity in envelope composition. Methanobacteria have a structure referred to as pseudomurein which resembles peptidoglycan, Methanosarcina have a structure referred to as methanochondroitin and Methanococcus and Methanoplanus have protein or glycoprotein layers. Pseudomurein is distinguished from peptidoglycan by its use of L-isomeric amino sugars with α -1,3 linkages rather than D-isomeric amino sugars using α -1,4 linkages. Haloarchaea have a protein layer containing a great excess of acidic amino acids whose negative charges counterbalance the high concentration of positively charged sodium ions in their salty environment. The envelope of Natronobacteria contains a novel layer composed of a glutamine polymer with N-acetylglucosamine, glucose and other sugars linked via the amide group of glutamine.

Archaeal cell membranes. Archaeal cell membranes are chemically unique from those of Bacteria or Eukarya. Differences include: (a) chirality of glycerol; (b) hydrocarbon-glycerol linkage; (c) isoprenoid chains; and (d) side-chain branching. The basic unit from which cell membranes are built is the phospholipid. The glycerol in archaeal phospholipids is a

stereoisomer (L-glycerol) of that found in bacterial and eukaryal membranes (D-glycerol). The side chains in the phospholipids of Bacteria and Eukarya are fatty acids usually 16–18 carbon atoms in length and are coupled to glycerol via an ester linkage. In Archaea, side chains are coupled via an ether linkage. Archaea have side chains built from isoprene. Isoprene is the simplest member of a class of chemicals called terpenes. The ester linked fatty acids of Bacteria are linear, whereas the ether linked hydrocarbons of Archaea are highly branched. Archaeal glycerol diether lipids form a true bilayer membrane, whereas archaeal glycerol tetraether lipids form lipid monolayers. Lipid monolayer membranes occur in certain methanogens, are widespread among hyperthermophilic Archaea and are thought to confer additional thermal stability. Archaeol (diphytanylglycerol diether) is the predominant membrane core lipid in most methanogens and all extreme halophiles. In contrast, cell membrane of hyperthermophilic archaea and a few methanogens contain caldarchaeol, a dibiphytanyldiglycerol tetraether. The production of ether-linked lipids is so distinctive in Archaea that it is used as a biomarker for detecting fossilized Archaea in micropaleontological studies of rocks, sediment cores and other ancient materials. The chemical difference between archaeal and bacterial lipids provides additional support for the evolutionary distance between the Archaea and Bacteria.

III. ECOLOGY, PHYSIOLOGY AND SYSTEMATICS OF THE ARCHAEA

The cultivated Archaea are distributed into two kingdoms, the Euryarchaeota and the Crenarchaeota (Table 7.2). A third kingdom called Korarchaeota consists of uncultivated members. Cultivated Archaea are divided into 12 orders, 20 families, and 69 genera (Boone *et al.*, 2001). Cultivated Euryarchaeota include all of the known methanogens and extreme halophiles as well as some extreme thermophiles. Cultivated members of the Crenarchaeota include other hyperthermophiles and most thermoacidophiles. In addition, many other archaeal taxa have been detected in a variety of environments using molecular phylogenetic methods. While as yet uncultivated, these Archaea also are distributed across both the euryarchaeotal and the crenarchaeotal kingdoms. Cultivated Archaea include terrestrial and aquatic members, and occur in diverse locations from anaerobic sediments to hypersaline pools and geothermally heated environments. Some also occur as symbionts in animal digestive tracts. Archaea

TABLE 7.2 Systematics of the Archaea

Orde	Family	Habitat	Features
<i>Kingdom: Euryarchaeota</i>			
Archaeoglobales	Archaeoglobaceae	Geothermally heated sites	Strict anaerobes, facultative chemolithoautotrophs, hyperthermophiles, neutrophiles
Halobacteriales	Halobacteriaceae	Ubiquitous in areas of high salt concentration like salt lakes, salterns	Aerobes or facultative anaerobes, require 3.5–4.5 M NaCl, chemoorganotrophs, usually mesophiles
Methanobacteriales	Methanobacteriaceae	Aquatic sediment, sewage digester, GI tract of animals	Strict anaerobes, chemolithoautotrophs, mesophiles to thermophiles
Methanococcales	Methanothermaceae	Hot solfataric fields	Strict anaerobes, chemolithotrophs, hyperthermophiles
	Methanococcaceae	Marine environments	Strict anaerobes, chemolithoautotrophs, mesophiles to thermophiles, selenium required
	Methanocaldococcaceae	Deep sea hydrothermal vents	Strict anaerobes, chemolithoautotrophs, hyperthermophiles
Methanomicrobiales	Methanocorpusculaceae	Lake sediments, digestors	Strict anaerobes, chemoorganotrophs, mesophiles
	Methanomicrobiaceae	Marine sediments, sewage digestors	Strict anaerobes, acetate required, chemolithoautotrophs, mesophiles to thermophiles
	Methanospirillaceae	Sewage sludge, waste digestors	Strict anaerobes, fix N ₂ , autotrophs or chemoorganotrophs, mesophiles
Methanopyrales	Methanopyraceae	Hot vents	Strictly anaerobic, chemolithoautotrophs, hyperthermophiles
Methanosarcinales	Methanosaetaceae	Sewage sludge and sediments	Strictly anaerobic, chemolithotrophs, mesophiles to thermophiles
	Methanosarcinaceae	Aquatic sediment, sewage digestors, GI tract of animals	Strictly anaerobic, N ₂ may be fixed, chemoautotrophs, mesophiles to thermophiles
Thermococcales	Thermococcaceae	Marine and terrestrial thermal environments	Strict anaerobes, heterotrophs, hyperthermophiles
Thermoplasmatales	Thermoplasmataceae	Self heating coal refuse piles, acidic solfataric fields	Wall-less, facultative aerobes, heterotrophs, thermoacidophiles
	Picrophilaceae	Hot geothermal solfataric soils and springs	Obligate aerobes, heterotrophs, hyperacidophiles
<i>Kingdom: Crenarchaeota</i>			
Desulfurococcales	Desulfurococcaceae	Marine environments, hot solfataric areas	Mostly anaerobic, chemolithotrophs or heterotrophs, hyperthermophiles
	Pyrodictiaceae	Hot sea floors, sediments, black smokers	Anaerobic, facultative chemolithoautotrophs, hyperthermophiles
Sulfolobales	Sulfolobaceae	Hot acidic solfataric springs	Aerobic or anaerobic, chemolithoautotrophs, S ⁰ metabolizers, extreme thermoacidophiles
Thermoproteales	Thermofilaceae	Solfataric hot springs	Strict anaerobes, organotrophs, thermoacidophiles
	Thermoproteaceae	Acidic hot springs	Anaerobes to facultative anaerobes, chemolithoautotrophs or organotrophs, hyperthermophiles
<i>Kingdom: Korarchaeota</i>			
Uncultivated Archaea delineated on the basis of 16 rRNA sequences			

Key: M, Molar; NaCl, sodium chloride; GI, gastrointestinal; N₂, nitrogen; S⁰, sulfur.

include aerobes, anaerobes and facultative anaerobes, chemolithotrophs, organotrophs and facultative organotrophs. Archaea can be mesophilic or thermophilic with some species growing at temperatures up to 110°C. Psychrophilic members have also been detected but not cultured. The Archaea often are

divided into three key biotypes; methanoarchaea, haloarchaea and hyperthermophilic Archaea (Madigan *et al.*, 2000; also see <http://www.ncbi.nlm.nih.gov:80/entrez/query.fcgi?db=Taxonomy>).

The methanogenic Archaea. The methanoarchaea belong to the Euryarchaeota and constitute

a phylogenetically unique biotype. Methane (CH₄) production is an integral part of their energy metabolism and this form of metabolism is still unique to the Archaea. Such organisms are called methanogens and the process of methane formation is called methanogenesis, which is the terminal step in biodegradation of organic matter in many anaerobic environments. Habitats of methanogens range from anoxic sediments such as swamps, and wastewater treatment facilities to ruminant digestive tracts. They can also be found as endosymbionts of various anaerobic protozoa. Most known methanogens are mesophilic although "extremophilic" species growing optimally at very high or very low temperatures or at very high salt concentrations have also been isolated. These are strict anaerobes that are able to form methane as the principal metabolic end product using various oxidized forms of one- and two-carbon compounds as terminal electron acceptors. Key genera of this group include; *Methanobacterium*, *Methanococcus*, and *Methanosarcina*.

The halophilic Archaea. This diverse group of Euryarchaeota inhabit highly saline environments such as solar evaporation ponds, natural salt lakes and surfaces of salted foods. Moderately halophilic Archaea require 2–4 M sodium chloride (12–23%) for optimal growth. Virtually all extremely halophilic Archaea grow at 5.5 M sodium chloride (32%) which is the limit of saturation of sodium chloride. Haloarchaea can be aerobic or facultatively anaerobic and are chemoorganotrophic. They are generally mesophilic but can be moderately thermophilic (growth up to 55°C). Some species contain a protein called bacteriorhodopsin and the carotenoid pigments, bacterioruberins, which are used for the light mediated synthesis of ATP. Presence of these proteins results in a distinct pigmentation leading to their red-purple coloration. *Halobacterium* employs potassium as a compatible solute to withstand high external sodium concentrations to ensure a positive water balance. Extreme halophilicity was thought to occur only in Archaea; recently, however, molecular phylogenetic evidence indicates Bacteria may also have this property. Key genera of the Haloarchaea include; *Halobacterium*, *Haloferax*, and *Natronobacterium*.

The thermophilic Archaea. A number of Archaea thrive in thermal environments. Those with growth optima at or above 80°C are called hyperthermophiles. Thermophilic Archaea inhabit terrestrial and marine regions with geothermal or hydrothermal intrusion. A growth requirement for extreme acid (acidophily) can accompany the thermophilic lifestyle. The sulfur- and sulfate-reducing thermophiles are split between members of the Euryarchaeota and the

Crenarchaeota. These are strict anaerobes using elemental sulfur as a terminal electron acceptor, which is reduced to hydrogen sulfide. These organisms are extremely thermophilic with growth up to 100°C. Members of the *Thermococci* and *Pyrococci* are Euryarchaeota. *Methanopyrus*, another Euryarchaeote, is a hyperthermophilic methanogen. Only *Archaeoglobus* is a true sulfate reducer, capable of reducing sulfate to hydrogen sulfide. Sulfur reducing Crenarchaeota include *Thermoproteus*, *Pyrodictium*, and *Pyrolobus*. *Pyrolobus fumarii* holds the current record for the most thermophilic of all known organisms, its growth temperature maximum is 113°C. Crenarchaeotal sulfur oxidizers include the *Sulfolobales*, which are found in acidic sulfur containing geothermal pools such as those found in Yellowstone National Park, USA (Fig. 7.2). These are obligate aerobes that use oxygen as a terminal electron acceptor and grow in the temperature range 70–90°C and at pH values of between 2 and 5. Acidophily is also found among members of two euryarchaeotal genera, *Thermoplasma* and *Picrophilus*, which are among the most acidophilic of all known prokaryotes. Most species of *Thermoplasma* have been obtained from self-heating coal refuse piles. *Thermoplasma* resemble the mycoplasma in having an envelope comprising of only a cytoplasmic membrane. *Picrophilus* is capable of growth even below pH 0. These organisms are both chemoorganotrophic. Again, members of the Bacteria share at least the thermophilic and hyperthermophilic biotypes of Archaea while extreme acidophily remains unique to the Archaea. Key genera of the thermophilic Archaea include; *Thermococcus*, *Pyrococcus*, *Pyrobaculum*, and *Sulfolobus*.

Archaea as non-extremophiles. The known phenotypes of cultivated Archaea are still largely represented by extreme halophiles, sulfur metabolizing thermophiles, and methanogens. This picture has altered as new methods have been applied to the study of uncultivated microbes. The presence of new types of uncultivated Archaea was first suggested during surveys of marine plankton. Surveys of polymerase chain reaction (PCR) amplified small subunit rRNA genes revealed archaeal rRNA sequences in deep ocean water samples. The discovery of high numbers of Archaea in a wide number of oceans and the association of a novel crenarchaeotal isolate with a marine sponge living at 10°C, provide further evidence of new archaeal biotypes native to cold seawater. Since their initial detection, evidence for widespread distribution of new uncultivated Archaea has been extended to include forest and agricultural soils, deep subsurface paleosols, freshwater lakes and various sediments.

FIGURE 7.2 Electron micrographs of *Sulfolobus solfataricus*. (A) transmission electron micrograph; (B) scanning electron micrograph. Both images show the irregular cell shape of the organism.

TABLE 7.3 Ecology and physiology of the model archaeal species

Genus	Biotype	Habitat	Energy metabolism	Energy source
<i>Methanococcus maripaludis</i>	Methanogen	Salt marsh sediment	Obligate anaerobes chemolithotrophs/	H ₂ + CO ₂ , pyruvate + CO ₂ , formate
<i>Methanosarcina acetivorans</i>	Methanogen	Marine sediment	Obligate anaerobes chemolithotrophs/	H ₂ + CO ₂ , methanol, methylamines, acetate
<i>Haloferax volcanii</i>	Halophile	Dead Sea	Usually obligate aerobic chemoorganotroph,	Amino acids
<i>Halobacterium salinarium</i>	Halophile	Hypersaline lakes and salted foods	Usually obligate aerobic chemoorganotroph,	Amino acids, organic acids
<i>Sulfolobus solfataricus</i>	Hyperthermophile	Sulfur-rich hot springs	Aerobic chemolithotrophs/ chemoorganotrophs	S ⁰ , H ₂ S, sugars, amino acids
<i>Sulfolobus acidocaldarius</i>	Hyperthermophile	Sulfur-rich hot springs	Aerobic chemolithotrophs/ chemoorganotrophs	S ⁰ , H ₂ S, sugars, amino acids

Key: H₂, hydrogen; CO₂, carbon dioxide; S⁰, sulfur; H₂S, hydrogen sulfide.

Archaeal model systems. As is the case with Bacteria, particular archaeal taxa are employed as model experimental systems to address mechanistic questions about this group of prokaryotes. The key feature distinguishing these species is their genetic systems. Among the Haloarchaea *Haloferax volcanii* and *Halobacterium salinarum* (including NRC-1) are employed. *Methanococcus maripaludis* and *Methanosarcina acetivorans*, are popular among the methanogenic Archaea, while among the thermophilic Archaea *Sulfolobus solfataricus* and *Sulfolobus acidocaldarius* are best studied (Table 7.3).

IV. MOLECULAR BIOLOGY OF THE ARCHAEA

The distinguishing feature of Archaea is their use of eukaryotic-like genes rather than bacterial-like genes for the synthesis, repair, and turnover of DNA, RNA, and protein (Table 7.4). Key aspects of this relationship have been recently described in greater detail (Blum, 2001). This striking example of gene conservation supports the idea of a shared or common evolutionary origin for Archaea and Eukarya. An understanding of these subcellular processes is therefore a prerequisite for appreciating their place in

TABLE 7.4 Comparative molecular biology of archaea

Characteristic	Archaea	Eukarya	Bacteria
Chromosomal DNA	Covalently closed circle	Linear DNA in nucleus	Covalently closed circle ^a
Introns in genes	Rare	Present	Rare
Operons	Present	Absent	Present
DNA recombination and repair	Eukaryal homologs of Rad proteins and others	Rad proteins	RecA protein
Chromosome packaging	Euryarchaeotes: Histones Crenarchaeotes: Nonhistone proteins	Histones	Nonhistone proteins
RNA polymerase	One (10–12 subunits, all eukaryal homologs)	Three (12–14 subunits)	One (4 subunits)
Promoter structure	TATA box	TATA box	–10 and –35 hexamers (Pribnow box)
Transcription factors	Eukaryal homologs of TBP, TFIIB, TFIIS	TBP, TFIIB, TFIIS and others	Sigma factor
mRNA Caps and Long Poly-A tails	No	Yes	No
Translation initiation	Eukaryal homologs of eIF2 α , β , and γ , eIF4A, eIF5	eIF2 α , β , and γ , eIF4A, eIF5	IF-1, IF-2, and IF-3
Initiator tRNA	Methionine	Methionine	Formylmethionine
Ribosomes	70 S	80 S	70 S
Protein folding	Eukaryal homologs of Prefoldin, NAC, TCP1	Prefoldin, TCP1, NAC	Hsp70 system (DnaK), GroELS, TF
Proteasome	Present	Present	Rare
Protein secretion	7.5 S SRP RNA complex	7.5 S SRP RNA complex	4.5 S SRP RNA and Sec system

^aFew exceptions.

Key: TBP, TATA box binding protein; TFIIB, transcription factor B; TFIIS, transcription factor S, eIF, eukaryotic Initiation factors; IF, initiation factors; NAC, nascent polypeptide-associated complex; TF, trigger factor; SRP, signal recognition particle.

biology and evolution and their relationship to bacterial prokaryotes.

DNA replication and packing. Two features distinguish archaeal DNA replication, initiation of DNA synthesis, and packing and condensation of DNA into eukaryal-like nucleosomes. Though the functions necessary for initiation of DNA replication are common between members of all domains, the relevant archaeal proteins bear strong sequence conservation to those found in Eukarya and not Bacteria. These include; origin recognition complex protein 1 (ORC1), single strand binding protein (RPA), primase, minichromosome maintenance protein (MCM), clamp loader (PCNA), ATP-dependent ligase, and primer removal protein (FEN1). In Eukarya, ORC and MCM proteins are used to coordinate DNA replication with cell cycle, perhaps this is true in Archaea. Archaeal DNA replication like that in Bacteria initiates at a single origin and proceeds in a bidirectional manner. In most Euryarchaeota, DNA is packaged into nucleosomes resembling eukaryotic tetrasomes called half nucleosomes (for information on archaeal histones, see: <http://www.biosci.ohio-state.edu/~microbio/Archaealhistones/>). These structures are evident in electron micrographs and consist of DNA complexed with archaeal histone proteins. These structures have the same histone-DNA stoichiometry,

DNA topology, DNA recognition, and nucleosome positioning features as those of Eukarya. In Eukarya nucleosomes provide an important means of regulating gene expression, their presence in many Archaea implicates the existence of similar processes. In contrast to the Euryarchaeota, DNA packaging in members of the Crenarchaeota mirrors that of Bacteria. Small positively charged and highly abundant DNA binding proteins are present with no evidence of ordered packing structure.

DNA recombination and repair. Processing of the DNA ends at a double strand break (DSB) in Bacteria employs the RecBCD enzyme. In contrast, it appears RecBCD is absent in Archaea, which instead employ homologs of Eukaryal proteins Mre11/Rad50 and Spo11. In Bacteria, homologous recombination involving DNA strand pairing and exchange is catalyzed by RecA. In Archaea RecA is absent and this critical step is mediated instead by a eukaryotic Rad51 homolog termed RadA. Subsequent resolution of holiday junctions to form recombinant DNA molecules appears to be mediated by archaeal-specific enzymes. Recombinational repair in Archaea is generally more similar to eukaryal repair largely based on the presence of RAD52-like proteins. Other types of repair in Archaea such as alkylation repair, and nucleotide excision repair, employ proteins

with homology to both Bacteria and Eukarya. Mismatch and error-prone repair are less studied, however, and the lack of archaeal MutS homologs suggests Archaea employ mechanisms unlike those of Bacteria for overcoming this type of DNA damage.

RNA synthesis, modification, and degradation. The general transcription apparatus of Archaea exhibits extensive overlap in both function and gene sequence with that of Eukarya. Transcription in Bacteria employs a fundamentally different system. Early studies on this topic supported the separation of Archaea from Bacteria. In Bacteria, the association of RNA polymerase (RNAP) with sigma factor confers on RNAP the ability to bind specifically to promoters. In Eukarya and Archaea, RNAP never has the ability to bind to promoters, but instead is recruited to the DNA by proteins that pre-associate at such sequences. The overlap between the archaeal and eukaryotic transcription systems include: homologous promoter structure, and homologs of TATA binding protein (TBP), TFIIB, TFIIS, and the complex RNAP enzyme itself consisting of more than 10 different subunits. Despite such intriguing evolutionary overlaps, the identity of the accessory regulatory components of Archaea, which must control rates of transcription initiation in response to metabolic and environmental stimuli is poorly understood.

rRNA methylation in Archaea occurs in an analogous fashion to Eukarya and not like Bacteria (see <http://rna.wustl.edu/snoRNAdb/>). Ribosomal RNA of Eukarya undergoes extensive posttranscriptional modification including the addition of between 50 and 100 2'-O-ribose methylations depending on the species. Such modifications are thought important in rRNA folding, stability, ribosomal protein binding and rRNA activity within the ribosome. Methylation is mediated by a ribonucleoprotein complex consisting of the protein fibrillarin and NOP56/58 and small antisense RNAs called snoRNAs. Each methylated position is targeted by a distinct snoRNA. The rRNA of Bacteria such as *E. coli*, in contrast, contain only four ribose methylations with no evidence of snoRNAs. It appears that all Archaea examined to date encode fibrillarin and NOP56/58 homologs. Extensive arrays of snoRNAs have also been identified in thermophilic Archaea.

A hallmark distinguishing Bacteria from Eukarya is the extremely short lifetime of bacterial mRNA. Direct measurements of archaeal mRNA stability indicate they have long halflives and therefore more closely resemble Eukarya (Bini *et al.*, 2002). In addition, Archaea appear to lack most of the key enzymes employed by Bacteria to degrade mRNA particularly those required for initial endonucleolytic cleavage and

3' to 5' exonuclease activity. They do encode however, enzymes for the processing, maturation, and degradation of stable RNA that are co-situated in a highly conserved locus distributed throughout the Archaea.

Protein synthesis, folding, and turnover. Like Bacteria, archaeal mRNAs are neither capped nor contain polyA tails of significant length. Initiation of bacterial translation depends on the interaction of sequences located 5' to the start codon with the 3' end of the 16S rRNA and initiation factors IF1, 2 and 3. In Eukarya, mRNAs are capped and have long polyA tails, and localization of the start codon by a specialized ribosomal preinitiation complex occurs via a scanning-type mechanism without involvement of rRNA. Surprisingly, comparative analysis of protein factors in Archaea involved in translation indicate a high degree of conservation with those of Eukarya. For translation initiation this includes homologs of eukaryal proteins; eIF1A, eIF2 α , β , and γ suggesting formation of a preinitiation complex analogous to that of Eukarya, as well as eIF4A and eIF5 implicating the use of a scanning-type mechanism to locate initiation codons. In Archaea, monocistronic genes and those located in promoter-proximal positions within polycistronic units, often lack rRNA complementary sequences to guide incoming ribosomes. They also lack untranslated RNA leaders such that the transcription and translation start sites coincide. In contrast, genes located within polycistronic units do have rRNA complementary sequences. These observations suggest Archaea may employ distinct mechanisms for the initiation of translation of different gene categories.

Protein folding in Archaea employs enzymes that are distinct from those found in Bacteria and homologous to those in Eukarya. In Bacteria the key protein folding enzymes include the chaperone system consisting of heat shock protein 70 (HSP70; DnaK), DnaJ and HtpG, and the chaperonin system consisting of HSP60 (GroEL), and GroES. The latter forms double ring toroidal structures readily observed by electron microscopy. Additional activities include enzymes involved in protein secretion, catalysts for protein folding, the small HSPs, and trigger factor (TF). In Bacteria, nascent proteins proceed from the ribosome to TF to the HSP70 system and thence to the HSP60 system. In Archaea, TF is not present, the HSP70 system is very rare and the HSP60 system is absent. In Archaea nascent polypeptides interact possibly with a homolog of the eukaryotic protein, NAC, and subsequently with a eukaryotic homolog of Prefoldin (GimC), which functionally replaces the action of the HSP70 system. Subsequently there is an interaction with an alternate chaperonin system homologous to the eukaryotic TCP1 protein.

The key mechanism employed in Archaea for protein degradation involves a multisubunit hollow barrel-like structure called the 20S proteasome. The same structure is universally present in Eukarya but only rarely present in Bacteria. The proteasome is readily observed by electron microscopy, being 15 nm in length and containing 28 subunits. When present in Bacteria, proteasomes are thought to have been acquired by horizontal transmission. The proteasome associates with ATPase regulatory components in the form of a cap increasing the size of the structure considerably. The eukaryotic ubiquitin protein targeting system is not evident in Archaea and though other energy dependent proteases exist in Archaea additional studies are necessary to determine their distribution and relationship to bacterial proteases.

Protein secretion. The translocation (secretion) of proteins through membranes in all organisms employs a ribonucleoprotein complex called signal recognition particle (SRP). To date, this appears to be the sole mechanism in Eukarya and Archaea, while Bacteria have the additional (Sec) system. SRP comprises RNA and associated proteins, which bind nascent polypeptides to promote their interaction and transfer across the cytoplasmic membrane. Archaea like Eukarya have a 7.5S SRP RNA while Bacteria have a smaller 4.5S RNA. The SRP protein components of Archaea (SRP19 and SRP54) are more similar to those of Eukarya though present in fewer numbers. Other components of the archaeal protein secretion system including the leader peptidase that removes a portion of the N-terminal end of secreted proteins, exhibit greater similarity to eukaryotic enzymes.

V. CONCLUSIONS

Archaea like Bacteria are prokaryotes with simple cell structures. They can be readily distinguished from Bacteria by differences in the structure and chemistry of their envelopes. With some exceptions they cannot generally be distinguished by biotype, physiology, or metabolism. The most striking difference which appears to unite the Archaea is their use of eukaryal-type genes often with unique functions, to make and process DNA, RNA, and protein. This latter feature has major

implications for the origin of life and the relationship between Archaea and the last common ancestral cell.

Attenuation, Transcriptional

Charles Yanofsky

Stanford University

GLOSSARY

antiterminator An RNA hairpin structure that generally contains several paired nucleotides that are essential for terminator formation. When these nucleotides are paired in the antiterminator they cannot participate in terminator formation.

attenuator A short DNA region that functions as a site of regulated transcription termination.

charged tRNA A transfer RNA bearing its cognate amino acid (e.g., Trp-tRNA^{Trp}).

leader peptide A peptide encoded by the leader segment of a transcript.

leader peptide coding region A short peptide coding region in the leader segment of a transcript.

RNA-binding attenuation regulatory protein An RNA-binding protein that binds to a specific RNA sequence and, by so doing, either promotes or prevents formation of a transcription terminator.

RNA hairpin structure A base-paired stem and loop structure that has sufficient stability to remain in the base-paired, hairpin configuration.

terminator (factor-dependent) An RNA sequence usually causing transcription pausing that serves as a site of factor-dependent transcription termination.

terminator (intrinsic) An RNA hairpin followed immediately by a sequence rich in U's. The terminator serves as a signal to RNA polymerase to terminate transcription.

transcription pausing A temporary pause or delay in RNA polymerase movement on its DNA template.

transcription pause structure An RNA hairpin that causes RNA polymerase to pause or stall during transcription.

transcription termination Cessation of RNA synthesis and release of transcript and DNA template from RNA polymerase.

transcriptional attenuation A mechanism used to regulate continuation vs termination of transcription.

Transcriptional Attenuation is the term used to describe a general transcription regulatory strategy that exploits various sensing events and molecular signals to alter the rate of transcription termination at a site or a site preceding one or more genes of an operon. Many mechanisms of transcriptional attenuation exist. Each regulates operon expression by responding to an appropriate molecule or event and determining whether transcription will or will not be terminated.

I. OBJECTIVES AND FEATURES OF REGULATION BY TRANSCRIPTIONAL ATTENUATION

It is evident that an appreciable fraction of the genetic material of each organism is dedicated to regulating gene expression. The ability to alter expression provides

the variability that an organism needs in order to initiate or respond to the many changes that are associated with or responsible for each physiological and/or developmental event. Initiation of transcription is perhaps the single biological act that is most often subject to regulation. There are numerous examples of “negative-acting” repressor proteins—proteins that inhibit transcription initiation by binding to their respective DNA operator site(s) within or in the vicinity of the regulated promoter. Similarly, there are many examples of “positive-acting” regulatory proteins that activate transcription by binding at specific DNA elements in the vicinity of the affected promoter. Both negative- and positive-acting regulatory proteins are commonly activated or inactivated by small or large molecules as well as by reversible processes, i.e., phosphorylation and dephosphorylation. However, transcription initiation is only one of several common metabolic events that may be modulated to alter gene expression. The two subsequent stages in transcription, transcript elongation and transcription termination, are also common targets for regulatory change. The principal advantages achieved by regulating these events is that different classes of molecules and different metabolic processes can participate in regulatory decisions. Thus, once transcription has begun, the nascent transcript is a potential target for a regulatory event. In addition, in prokaryotes, in which most transcripts are initially translated as they are being synthesized, components of the translation machinery may participate in regulatory decisions. By exploiting these additional targets, organisms have greatly increased their regulatory options. A separate objective may have been to devote as little unique genetic information as possible to a regulatory process. Accordingly, some of the transcriptional attenuation regulatory mechanisms that will be described use less than 150 bp of DNA to achieve gene- or operon-specific control. Often attenuation regulation is achieved using only the common cell components that participate in RNA and protein synthesis. In this article, I review the features of several examples of regulation by transcriptional attenuation.

II. MECHANISMS OF TRANSCRIPTIONAL ATTENUATION

A. Regulation of termination at an intrinsic terminator

Many operons regulated by transcriptional attenuation contain a DNA region that specifies a RNA

sequence that can fold to form a hairpin structure followed by a run of U's, a structure called an intrinsic terminator. Intrinsic terminators instruct RNA polymerase to terminate transcription. The region encoding the intrinsic terminator is located immediately preceding the gene or genes that are being regulated. The transcript segment before and including part of the terminator often contains a nucleotide sequence that can fold to form a competing, alternative hairpin structure called the antiterminator. The existence of this structure prevents formation of the terminator. Antiterminator and terminator structures generally share a short nucleotide sequence, which explains why prior formation of the antiterminator prevents formation of the terminator. Additional features of the nucleotide sequence preceding or following a terminator or antiterminator can influence whether these structures will form or act. The transcript segment preceding the terminator often contains sequences that allow the organism to sense a relevant metabolic signal and to respond to that signal by allowing or preventing antiterminator or terminator formation.

A variety of mechanisms are used to sense specific cell signals. In operons concerned with amino acid biosynthesis, ribosome translation of a peptide coding region rich in codons for a crucial amino acid is often used to sense the presence or absence of the corresponding charged tRNA. Depending on the location of the translating ribosome on the transcript, an antiterminator will or will not form. In another example, in an operon concerned with pyrimidine biosynthesis, coupling of RNA synthesis with translation is employed to sense the availability of a nucleotide needed for RNA synthesis. In some mechanisms, RNA-binding proteins regulate termination. These proteins bind to specific transcript sequences or structures and allow or prevent antiterminator or terminator formation. One common regulatory mechanism is designed to sense the relative concentrations of a charged and uncharged tRNA and, depending on which is in excess, induce formation of an antiterminator or terminator. It is evident from these and other examples that regulation of the formation of an intrinsic terminator is a common strategy used to alter operon expression.

1. Ribosome-mediated attenuation

Synthesis of most proteins requires not only the availability of all 20 amino acids but also these amino acids must be in their activated state, covalently attached to their respective tRNAs. As such, they are primed for participation in polypeptide synthesis. The intracellular concentration of each amino acid reflects a balance

of several events, including rates of synthesis, utilization, import from the environment, and release from proteins by degradation. Occasionally, induction of a degradative pathway also affects the cellular level of an amino acid. The concentration of a specific charged tRNA also reflects several events, including the presence of the corresponding amino acid, its rate of charging onto tRNA, the availability of that tRNA, and use of that charged tRNA in protein synthesis. Other factors also affect the rate of protein synthesis, such as whether there are rare codons in the coding region being translated and whether all needed species of charged tRNA are available. The availability of free ribosomes and accessory molecules required for protein synthesis also has an impact on the rate of protein synthesis. Given these many variables, it is not surprising that so many attenuation mechanisms are used to sense and respond to specific cellular needs.

a. The *trp* operon of *Escherichia coli*

Transcription of the *trp* operon of *E. coli* is regulated by both repression and transcriptional attenuation. The initial event in regulation by attenuation is the formation of a RNA hairpin structure that directs the transcribing RNA polymerase molecule to pause after initiating transcription (Fig. 8.1, stage 1). This transcription pause provides sufficient time for a ribosome to bind to the ribosome binding site of a peptide coding region in the leader transcript and initiate translation (Fig. 8.1, stage 2). The moving ribosome in fact releases the paused polymerase, permitting resumption of transcription (Fig. 8.1, stage 3). Thereafter, transcription and translation proceed in unison. As the polymerase molecule transcribes the leader region, the translating ribosome moves along the transcript and reaches a segment that is capable of folding to form an antiterminator structure. However, whether or not this structure forms depends on the location of the translating ribosome. In a bacterium deficient in charged tRNA^{Trp}, the translating ribosome would stall over either of two adjacent Trp codons in the leader peptide coding region (Fig. 8.1, stage 4). Stalling would allow a downstream RNA segment to fold and form an antiterminator hairpin structure. As transcription proceeds, persistence of the antiterminator would prevent formation of the terminator since paired nucleotides at the base of the antiterminator must be free for terminator formation to occur. Under these conditions, transcription would continue into the structural genes of the operon. In a cell with adequate levels of charged tRNA^{Trp} (Fig. 8.1, stage 4 alternate), the tandem Trp codons would be translated and the

FIGURE 8.1 Stages in ribosome-mediated transcriptional attenuation regulation of the *trp* operon of *E. coli*. Transcription initiation and pausing (stage 1), ribosome loading (stage 2), and initiation of translation and release of the pause transcription complex (stage 3) occur under all conditions. When a cell is deficient in tryptophan-charged tRNA^{Trp} (stage 4), the translating ribosome stalls at either of the two Trp codons in the leader peptide coding region. Stalling permits the antiterminator to form; this prevents terminator formation, allowing transcription to continue into the structural genes of the operon. When a cell has sufficient charged tRNA^{Trp} to support ongoing protein synthesis (stage 4 alternate), translation proceeds to the leader peptide stop codon. A ribosome at this position blocks formation of the antiterminator structure and permits the terminator to form and cause termination.

translating ribosome would proceed to the leader peptide stop codon. At this position, the ribosome would block formation of the antiterminator and allow the terminator to form; hence, transcription would be terminated.

The leader regions of many bacterial operons, such as the *his*, *phe*, *leu*, *thr*, *ilvGMEDA*, and *ilvBN* operons, are organized much like that of the *trp* operon of *E. coli*. These operons appear to be regulated by the same mechanism, with only minor variations tailored to each operon's needs. Generally, the leader region sequence and organization reflects differences in regulatory requirements. For example, transcription of the *his* operon of *S. typhimurium* is regulated only by attenuation, unlike transcription of the *trp* operon of *E. coli* which is regulated by both repression and attenuation. The *his* operon's leader peptide coding region contains seven consecutive His codons. This organization allows greater sensitivity to changes in the cellular level of charged tRNA^{His}; a slight reduction is sufficient to delay ribosome movement through the His codon region. Any delay promotes antiterminator formation. An operon with a leader region that is organized differently is the *ilvGMEDA* operon of *E. coli*. Here, attenuation is regulated in response to the availability of three charged tRNAs those for tRNA^{Ile}, tRNA^{Val}, and tRNA^{Thr}. Codons for these tRNAs are arranged in the leader peptide coding region so that a deficiency of any of these charged species would promote antiterminator formation. Another operon regulated similarly is *pheST* of *E. coli*. This operon specifies the two polypeptides of phenylalanyl-tRNA synthetase. Translation of its leader peptide coding region containing five Phe codons is used to regulate termination/antitermination. An interesting consideration that bears on *pheST* operon regulation is that the product of this operon, phenylalanyl-tRNA synthetase, is needed under all growth conditions.

b. The *pyrBI* operon of *E. coli*

Another well-studied example in which ribosome-mediated attenuation regulates transcription of an operon concerns the *pyrBI* operon of *E. coli*. When a cell has inadequate levels of UTP for RNA synthesis, the UTP deficiency triggers transcription antitermination in the leader region of this operon (Fig. 8.2). Continued transcription of the operon allows the cell to increase its rate of pyrimidine nucleotide synthesis. The *pyrBI* leader transcript has several features that explain its role in transcription regulation. It can fold to form alternative antiterminator and terminator structures. In addition, the leader segment contains the coding region for a leader peptide; this coding segment overlaps the antiterminator and terminator. The leader transcript also has several U-rich sequences which play a role in transcription pausing. When the UTP level is insufficient to sustain continued RNA

FIGURE 8.2 Stages in transcriptional attenuation in the *pyrBI* operon of *E. coli*. When a cell is deficient in UTP, the RNA polymerase molecule that is transcribing the *pyrBI* operon leader region pauses at one or more UTP deficiency-dependent pause sites (stage 1). While the polymerase is paused a ribosome binds to the leader transcript and initiates translation (stage 2). When the polymerase is released, the translating ribosome moves closely behind the transcribing polymerase. Continued translation by this ribosome prevents formation of the terminator structure; thus, transcription continues into the structural genes of the operon (stage 3). When there are adequate levels of UTP to support rapid RNA synthesis (bottom) the transcribing polymerase pauses very briefly in the leader region and then continues transcription. The terminator sequence is formed well before the translating ribosome can approach this segment of the transcript. Terminator formation results in termination.

synthesis, the polymerase transcribing the *pyrBI* operon stalls at these U-rich pause sites (Fig. 8.2, stage 1). Reduced polymerase migration allows sufficient time for a ribosome to bind to the transcript and move closely behind the polymerase (Fig. 8.2, stage 2). A translating ribosome at this position could prevent formation of the terminator structure; thus, transcription of the operon would continue (Fig. 8.2, stage 3). When a cell has an adequate level of UTP, the transcribing polymerase molecule moves through the pause sites rapidly and is positioned well ahead of the

translating ribosome. This separation permits the terminator to form and cause transcription termination. Transcription of this operon is also regulated by an unrelated UTP-dependent mechanism.

c. Other examples

A related although different mechanism of ribosome-mediated transcription attenuation is used to regulate expression of the *ampC* operon of *E. coli*. The regulatory region of this operon, preceding *ampC*, encodes a leader transcript segment containing a ribosome binding site, adjacent start and stop codons, and a sequence that can form an intrinsic terminator. Expression of this operon is subject to growth rate regulation. During rapid growth, when the ribosome content per cell is high, a ribosome is likely to bind at the ribosome binding site in the leader segment and interfere with terminator formation. Under these conditions, transcription of the operon will continue. When the ribosome content per cell is low, the leader segment of the transcript is likely to be ribosome free for a period sufficiently long to allow the terminator to form and promote termination. An antiterminator is not used in this attenuation mechanism.

2. Binding protein-mediated attenuation

In several operons regulated by transcriptional attenuation, specific RNA-binding proteins determine whether or not transcription will be terminated. These proteins recognize specific sites or sequences in a transcript and, by binding, regulate formation of an antiterminator or terminator. Well-studied examples include the *bgl* operon of *E. coli* and the *sac* operon of *Bacillus subtilis*, which are regulated similarly, and the *trp* and *pyr* operons of *B. subtilis*, which are regulated differently. The RNA-binding regulatory proteins that regulate transcription of these operons function much like the stalled ribosome in amino acid biosynthetic operons, as described previously.

a. The *bgl* operon of *E. coli*

The *bgl* operon of *E. coli*, *bglG*–*bglF*–*bglB*, is a three-gene operon encoding proteins required for the utilization of β -glucosides as carbon sources. The operon contains two independent sites of regulated transcription termination, the first before *bglG* and the second between *bglG* and *bglF*. The products of the first two genes of the operon, BglG and BglF, are necessary for regulation of this operon by attenuation. BglG exists in two forms: a phosphorylated, monomeric, inactive species and a dephosphorylated, dimeric, active

(RNA-binding) species (Fig. 8.3). BglF is a membrane-bound phosphoenolpyruvate-dependent phosphotransferase. When BglF senses a β -glucoside, it phosphorylates the sugar and transports it into the cell. Substrate-activated BglF also dephosphorylates BglG, converting it into the active, RNA-binding dimeric form. In the absence of a β -glucoside, BglF phosphorylates BglG, rendering it monomeric and inactive.

The transcript segment preceding *bglG* and *bglF* can fold to form either an antiterminator or a terminator structure. When BglG is dephosphorylated and active, it binds to and stabilizes the antiterminator (Fig. 8.3). Since the stem of the antiterminator contains bases that are part of the terminator, the terminator does not form. Nucleotides in the single-stranded loop region of each antiterminator as well as paired bases in the antiterminator stem appear to be the sites of BglG binding. BglG is believed to act similarly at the two antiterminators. When BglG is inactive and the *bgl* operon is being transcribed, terminator structures form in the transcript and terminate transcription (Fig. 8.3).

The *sacB* and *sacPA* genes of *B. subtilis*, genes concerned with sucrose utilization, appear to be regulated by a very similar antitermination/termination mechanism. The protein products of genes *sacY* and

FIGURE 8.3 Protein-mediated transcriptional attenuation in the *bgl* operon of *E. coli*. In the presence of a β -glucoside carbon source the BglF protein phosphorylates the sugar and transports it into the cell (top). β -Glucoside-activated BglF also dephosphorylates the BglG protein. Dephosphorylated BglG dimerizes, and the dimer binds at one or both of the antiterminators in the transcript of the *bgl* operon, stabilizing the antiterminator structure. The existence of the antiterminator prevents formation of the terminator; thus, transcription proceeds. In the absence of a β -glucoside BglF phosphorylates BglG and the phosphorylated form remains as a monomer, incapable of binding to RNA (bottom). Under these conditions, the antiterminator is not stabilized, and the terminator forms, terminating transcription.

sacT regulate *sacB* and *sacPA* expression, respectively. The leader regions preceding *sacB* and *sacPA* specify RNA antiterminator structures that closely resemble those of the *bgl* operon. Dephosphorylation of SacY by SacX, in response to the presence of sucrose, leads to antitermination of transcription in the leader region preceding *sacB*. The proteins and sites involved in attenuation control in the *sac* and *bgl* systems are homologous.

b. The *trp* operon of *B. subtilis*

The leader segment of the transcript of the *trp* operon of *B. subtilis* can fold to form mutually exclusive antiterminator and terminator structures (Fig. 8.4). When a cell is deficient in tryptophan and the leader region of the operon is being transcribed, the antiterminator forms, preventing terminator formation and termination (Fig. 8.4). In the presence of excess tryptophan, an RNA-binding protein, TRAP (*trp* RNA-binding attenuation protein), encoded by the *mtrB* gene, binds tryptophan and becomes activated. Activated TRAP can bind to the *trp* operon leader transcript while it is being synthesized. The TRAP binding site consists of a series of U/GAG repeats located immediately preceding and including part of the antiterminator structure (Fig. 8.4). TRAP binding to the

FIGURE 8.4 Protein-mediated transcriptional attenuation in the *trp* operon of *B. subtilis*. When a cell is deficient in tryptophan the TRAP protein is not active, the leader region of the *trp* operon is transcribed, the antiterminator forms, and transcription continues into the operon (top). When a cell has sufficient tryptophan to support rapid growth, the TRAP protein is activated by bound tryptophan (bottom). Activated TRAP binds at U/GAG repeat sequences (small boxes) in the transcript segments located before and within the antiterminator. Bound TRAP essentially melts the antiterminator, allowing a sequence at the base of the antiterminator to exist in an unpaired form. This unpaired sequence participates in the formation of the terminator hairpin structure, which promotes termination.

transcript prevents formation of the antiterminator, thereby promoting formation of the terminator. The 3D structure of TRAP has been described, and the residues in the protein principally responsible for RNA binding have been identified. The protein is doughnut shaped and consists of 11 identical subunits, each of which associates with a U/GAG sequence in the transcript. TRAP is believed to wrap the single-stranded leader transcript around its periphery and, by so doing, prevent formation of the antiterminator.

Tryptophan-activated TRAP also binds to a similar sequence of U/GAG repeats that precede the *trpG* coding region. *trpG* is the sole *trp* gene of *B. subtilis* that is not in the *trp* operon. *trpG* is located in a folate operon and specifies a bifunctional polypeptide that functions both in tryptophan and in folate biosynthesis. A TRAP binding site overlaps the *trpG* ribosome binding site; thus, TRAP binding inhibits translation of *trpG*. TRAP action therefore coordinates *trp* gene expression in the folate and tryptophan operons.

c. The *pyr* operon of *B. subtilis*

Another example of transcriptional attenuation mediated by a RNA-binding protein concerns regulated expression of the *pyr* operon of *B. subtilis*. This organism produces a novel uracil phosphoribosyltransferase, PyrR, that also functions as a RNA-binding transcription regulator. PyrR can bind at similar sites in three ~150-nt untranslated segments of the *pyr* transcript, each preceding a polypeptide coding segment and each containing a terminator. The first terminator precedes the first gene in the operon, *pyrR*, which in fact encodes this RNA-binding regulatory protein/enzyme. The second terminator is located between *pyrR* and *pyrP*; *pyrP* encodes a uracil permease. The third terminator is located between *pyrP* and *pyrB*. *pyrB* specifies aspartate transcarbamylase. Each of the three untranslated transcript segments can fold to form an alternative antiterminator structure that can prevent formation of an intrinsic terminator. In addition, each untranslated transcript segment can form a third structure, earlier in the transcript, termed an anti-antiterminator. This structure includes part of the antiterminator; thus, its formation prevents formation of the antiterminator. When plentiful PyrR binds to the nascent *pyr* operon transcript and stabilizes the anti-antiterminator stem-loop structure. Stabilization of this structure blocks formation of the antiterminator structure, promoting formation of the terminator and thereby causing termination. When cells are deficient in pyrimidines and PyrR is inactive the antiterminator prevents formation of the terminator, allowing transcription to continue.

The three antiterminators are predicted to be the most stable of the several RNA structures. PyrR's RNA binding ability is responsive to the relative concentrations of UMP and PRPP, with bound UMP favoring RNA binding and bound PRPP preventing UMP binding and activation of the protein.

The 3D structure of PyrR of *B. subtilis* has been determined. The RNA sequences that are recognized have also been identified. Several bacterial species appear to produce homologs of PyrR and to regulate their *pyr* operons by the same or a similar mechanism.

The organization of the leader region of the *pur* operon of *B. subtilis* suggests that this operon is regulated by transcription termination/antitermination in response to changes in the availability of guanine nucleotides.

d. The S10 operon of *E. coli*

The 11-gene S10 ribosomal protein operon of *E. coli* contains a 172-base pair leader regulatory region which is used to achieve protein-mediated transcriptional attenuation. The S10 operon is regulated autogenously; that is, the product of one of its structural genes, protein L4, binds to the S10 leader transcript and regulates transcription termination. L4 binding also inhibits translation of coding regions of the operon. The transcript of the leader region forms multiple hairpin structures, two of which are essential for L4 activity. During transcription of the leader region RNA polymerase pauses after synthesizing one of these hairpins, a potential intrinsic terminator. Pausing at this site is enhanced *in vitro* by bound NusA protein and, most important, the pause complex is further stabilized by bound L4 protein. Enhanced stabilization of the terminator hairpin is believed to be responsible for efficient transcription termination. The leader RNA terminator structure, hairpin HE, participates in these events. An additional hairpin, HD, just preceding hairpin HE, also influences termination. How the structure HD is involved is not understood.

3. tRNA-mediated attenuation

a. tRNA synthetase operons of *B. subtilis*

In *B. subtilis* and other gram-positive bacteria, many operons encoding aminoacyl-tRNA synthetases, and some operons encoding amino acid biosynthetic enzymes, are regulated by tRNA-mediated transcriptional attenuation (Fig. 8.5). Each of these operons contains a leader region that specifies a transcript segment that can fold to form a complex set of structures, two of which are mutually exclusive and function as

FIGURE 8.5 Uncharged tRNA-mediated transcriptional attenuation in tRNA synthetase and amino acid biosynthetic operons of *B. subtilis* and other gram-positive bacteria. When a bacterial cell is defective in charging a tRNA with the corresponding amino acid, the uncharged tRNA pairs with the leader transcript of the operon specifying the tRNA synthetase that charges that amino acid. Two segments of the tRNA are believed to be involved in RNA-RNA pairing. One segment, the anticodon of the tRNA, is thought to pair with a complementary sequence in a side bulge in the leader transcript, called the specifier. The acceptor end of the tRNA is also believed to pair with the leader transcript. Its target is a single-stranded bulge sequence in the antiterminator, called a T box. Pairing of the uncharged tRNA at these two sites is proposed to stabilize an antiterminator structure, thereby preventing formation of the terminator (top). When the relevant tRNA is mostly charged, it cannot pair with the T box sequence. The leader RNA then folds to form the terminator structure, which terminates transcription (bottom).

antiterminator and terminator. Translation is not used to choose between these alternative RNA structures. Rather, each leader RNA is designed to recognize the accumulation of an uncharged tRNA species as the signal to prevent termination. The crucial recognition sequence in leader RNA includes a single-stranded segment with a triplet codon, designated the specifier sequence (Fig. 8.5). The triplet specifier is located in a side bulge of a RNA hairpin structure. The specifier sequence is complementary to the anticodon of the tRNA that is a substrate of the tRNA synthetase that is being regulated. In amino acid biosynthetic operons regulated by this mechanism, this triplet codes for the amino acid that is synthesized by the proteins specified by the operon. A second tRNA binding site, termed a T box, located within a side bulge in the antiterminator, is complementary to nucleotides preceding the acceptor end of the tRNA (Fig. 8.3). The current regulatory model (Fig. 8.5) predicts that when an uncharged tRNA is plentiful, it binds to the specifier and T box of an appropriate leader RNA, stabilizing the antiterminator

and thereby preventing terminator formation. When the tRNA is charged, its acceptor end is blocked by an amino acid and thus it cannot pair with the T box. Under these conditions, the terminator will form, resulting in transcription termination. The charged tRNA apparently is still recognized because it competes with uncharged tRNA. Switching the codon in a leader RNA can change the specificity of the response. Although the events described only concern interactions between tRNA and leader RNA, unidentified factors may also participate.

B. Regulation of termination at a factor-dependent terminator

In many bacterial species there is a second class of transcription termination sites—factor-dependent sites—at which a specific protein, Rho, interacts with RNA polymerase and causes termination. Rho-dependent termination requires an unstructured RNA segment as a site of Rho binding and a downstream RNA segment as a site of RNA polymerase pausing and termination. Accessory proteins that interact with RNA polymerase or with Rho also influence the termination process. Generally, once Rho binds to a transcript it migrates in the 3' direction until it contacts a stalled polymerase. When it does, it can trigger the act of termination. Rho-dependent termination sites are not intrinsic terminators.

1. *N* protein-mediated antitermination in phage λ

The earliest studied and most thoroughly analyzed example of regulation by transcription termination/antitermination involves the action of the N protein of bacteriophage λ in mediating antitermination at sites of Rho-dependent termination in the phage genome. Regulation at these sites controls expression from major leftward and rightward phage promoters. N protein functions by interacting with RNA polymerase, forming an antitermination complex. This requires *cis*-acting transcript sites and sequences, called nut sites. These sites are composed of two elements, a BoxA sequence and a BoxB sequence. Box-B folds to form a hairpin loop structure. N associates with BoxB, and several host proteins associate with N and RNA polymerase in the formation of the antitermination complex. Other proteins in the complex either recognize the BoxA sequence or associate with N and the transcribing RNA polymerase complex. The fully formed N protein–RNA polymerase antitermination complex is resistant to the action of Rho. This antitermination complex can transcribe through intrinsic terminators as well as sites of Rho-dependent termination.

There are other examples, particularly in bacteriophage, in which specific viral proteins mediate antitermination events. In these instances, the mechanisms of antitermination vary somewhat from the mechanism attributed to the N protein. In addition, the ribosomal RNA operons of *E. coli* are known to be regulated by an antitermination mechanism that prevents Rho-dependent termination. This system has several features in common with N-mediated antitermination, including use of some of the same proteins and similar RNA binding sites.

2. Translation-mediated antitermination in the *tna* operon

Escherichia coli and other bacteria contain operons that encode enzymes that can degrade specific amino acids, making them available as carbon and/or nitrogen sources. The tryptophanase (*tna*) operon of *E. coli* is one example. This operon encodes two polypeptides—one that degrades tryptophan and another that transports tryptophan into the cell. Transcription of the structural genes of this operon is subject to regulation by transcriptional attenuation. Transcription initiation in the operon is regulated by catabolite repression. Attenuation is mediated by a mechanism that involves tryptophan-induced transcription antitermination. The antitermination process prevents Rho from terminating transcription at specific sites in the leader region of the operon. The transcript of the leader region contains a short peptide coding region, *tnaC*, which has a single Trp codon. Synthesis of the 24-residue TnaC peptide, with its crucial Trp residue and certain other key residues, is essential for antitermination. In the presence of inducing levels of tryptophan the nascent TnaC peptide is believed to act in *cis* on the ribosome engaged in synthesizing the peptide, inhibiting its release at the leader peptide stop codon. Ribosome release at this stop codon is thought to be essential for termination since release is required to expose a presumed Rho entry/binding site in the vicinity of the *tnaC* stop codon. How the inducer tryptophan is recognized is not known, nor is it known how the leader peptide interacts with the translating ribosome to block its release at the *tnaC* stop codon.

III. CONCLUSIONS

The transcriptional attenuation mechanisms described previously achieve operon-specific regulation by modifying one or more biological events that influence transcription termination. Use of these mechanisms greatly expands the regulatory capacity

of each organism. An additional advantage is that these mechanisms permit a facile adjustment of the basal level of expression of an operon—expression in the absence of signals that regulate termination. Thus, variations in RNA structure, stability, or arrangement can establish an appropriate basal level of operon expression. In addition, as mentioned previously, some transcriptional attenuation mechanisms are economical because they require little unique genetic information. In eukaryotes there are several examples of regulated transcription delay with features resembling those of some of the attenuation mechanisms that were described.

Bacillus subtilis, Genetics

Kevin M. Devine

Trinity College, Dublin

GLOSSARY

competence Development of the ability to bind and internalize DNA from the medium.

endospore A metabolically quiescent cell that is resistant to desiccation, ultraviolet light, and other environmental insults.

forespore The cell compartment of the sporangium destined to become the spore.

integrating plasmid A plasmid that cannot replicate autonomously in a host bacterium. It can, however, establish itself by integration into the chromosome through recombination between homologous plasmid and chromosomal sequences.

mother cell The compartment of the sporangium which engulfs the forespore, synthesizes spore coat proteins, and lyses when the mature endospore is formed.

polymerase chain reaction Amplification of specific DNA sequences *in vitro* using oligonucleotide primers and thermostable DNA polymerase.

sigma factor A transcription factor which recognizes specific DNA sequences and directs RNA polymerase to initiate transcription at these sites.

SOS response A regulon that is induced to protect cells against DNA damage.

sporangium The developing bacterial cell.

sporulation The developmental process whereby the bacterial cell forms a quiescent spore.

two-component system A signal transduction system composed of a sensor kinase and a response

regulator. The kinase is activated when it senses some environmental or nutritional parameter. It then activates the response regulator, which alters gene expression in a manner that allows the bacterium to respond to the prevailing conditions.

Bacillus subtilis is an endospore-forming, gram-positive, rod-shaped bacterium. Several characteristics of *B. subtilis* have attracted intense interest and therefore it has become a model system for bacterial research. It produces enzymes that are widely used in the brewing, baking, and washing powder industries.

Because its products have traditionally been used in the food industry, *B. subtilis* is classified as a GRAS organism (generally regarded as safe) and is therefore a natural choice of host for the production of heterologous proteins using recombinant DNA methodology. *Bacillus subtilis* cells become naturally competent during the transition between exponential growth and the stationary phase of the growth cycle. Competent cells have the ability to bind and internalize DNA present in the medium. Therefore, although the regulation of competence development has attracted research interest, competence development has provided the means through which *B. subtilis* can be readily genetically manipulated. This has led to the development of sophisticated molecular techniques, primarily based on integrating plasmids and transposons, for genetic analysis.

Spore formation is a developmental process whereby a vegetative cell undergoes a series of morphological

events to become a metabolically quiescent spore. This process involves temporal and spatial regulation of gene expression and communication between the forespore and mother cell of the sporangium. These features make spore formation in *B. subtilis* an attractive model system to study development. The complete genome sequence of *B. subtilis* was published in November 1997. This knowledge has greatly expedited research efforts in this bacterium. It has also revealed that the genome encodes many genes that cannot be assigned a function. The challenge now is to determine how these genes contribute to the cellular metabolism and physiology.

I. CHARACTERISTICS OF BACILLUS SUBTILIS

A. Taxonomy and habitat

The genus *Bacillus* consists of gram-positive, endospore-forming, rod-shaped bacteria. There are more than 70 species, which display wide morphological and physiological diversity. Only 2 (*B. anthracis* and *B. cereus*) are known to be human pathogens. The defining feature of the genus is endospore formation. The genus is subdivided into six groups using a variety of morphological (particularly sporangial) and metabolic criteria. *Bacillus subtilis* belongs to group II, whose distinguishing features are (i) the formation of an ellipsoidal spore which does not swell the mother cell, (ii) the ability of cells to grow anaerobically with glucose as the carbon source in the presence of nitrate, and (iii) the production of acid from a variety of sugars.

The natural habitat of *B. subtilis* is the soil, but it is also found in fresh water, coastal waters, and oceans. The ubiquity of the bacterium is probably a consequence of endospore formation, which allows survival after exposure to even the most hostile environments. *Bacillus subtilis* is also associated with plants, animals, and foods and is found in animal feces. The significance of these associations is not clear. It is thought that its presence in feces is merely the result of ingestion and passage through the gut, whereas a synergistic relationship may exist with plants in which the bacterium enhances the supply of nutrients.

B. Development of competence

Bacillus subtilis cells become competent naturally. Competence is the ability to bind and internalize exogenous DNA from the medium. This capability develops during nutrient limitation when cells are in

transition between exponential growth and the stationary phases of the growth cycle. Only 10% of the cell population becomes competent. The competent and non-competent fractions can be separated using renograffin gradients indicating that they are morphologically distinguishable. Competent cells can also be distinguished because they do not engage in either macromolecule or nucleotide synthesis and the SOS response is induced.

The mechanics of DNA binding and internalization have been established. DNA fragments of heterogeneous size adhere noncovalently to approximately 50 binding sites on the cell surface. DNA binding is not sequence specific. The DNA is then fragmented randomly. During internalization, one strand (chosen randomly) is degraded while the other is transported into the cytoplasm. Internalized DNA fragments are approximately 10 kilobases in size. The nature of the transforming DNA determines its fate: DNA that is homologous to the bacterial chromosome will form a heteroduplex with the chromosome leading to homologous recombination. Plasmid DNA will be established as autonomously replicating molecules.

C. Enzyme and antibiotic production

Bacillus species produce a range of enzymes and antibiotics in response to nutrient limitation. The enzymes include proteases, amylases, cellulases and lipases. Production is maximal when cells are in the stationary phase of the growth cycle. Production of these enzymes is presumably a survival strategy to scavenge macromolecular energy sources when nutrient levels are low. Many of these enzymes are widely used in the food, brewing, and biological washing powder industries. Enzymes with useful properties, such as thermostability, activity over a wide pH range, activity in detergents and oxidizing environments, have been identified in many *Bacillus* species. The role of *B. subtilis* in the enzyme industry is twofold: (i) Many *Bacillus* species are refractory to genetic analysis and *B. subtilis* is therefore the organism of choice to study the regulation of enzyme production and (ii) heterologous genes encoding enzymes with desirable properties can be cloned into *B. subtilis* strains which have been manipulated to give high product yields.

Bacillus species also produce antibiotics when cells enter the stationary phase of the growth cycle. This is probably a strategy to limit bacterial competition for the energy sources liberated through macromolecular degradation by the scavenging enzymes. *Bacillus subtilis* produces a range of peptide antibiotics, including subtilin, surfactin, bacillomycin, bacilysin,

and fengycin, that display a range of antibacterial and antifungal activities. Although the synthesis of these antibiotics and their role(s) in bacterial cell physiology and survival are academically interesting, they are not of great medical importance. They are synthesized by a variety of mechanisms: For example, subtilin is a lantibiotic (contains the modified amino acid lanthionine) which is produced ribosomally, whereas surfactin is produced by the multienzyme thiotemplate mechanism. The complete genome sequence (see Section II) has revealed many of the loci encoding enzymes for antibiotic synthesis: for example, *pks* encodes a polyketide synthase, *srf* encodes surfactin synthetase, and *pps* encodes a peptide synthetase. These three loci comprise 4% of the total genome length.

D. Sporulation

Bacillus subtilis undergoes spore formation in response to carbon, nitrogen, or phosphate limitation. This process results in the formation of a metabolically quiescent cell that is resistant to desiccation, ultraviolet (UV) light, and other environmental insults. The

process of sporulation involves temporal and cell type-specific regulation of gene expression, intercellular communication (between mother cell and forespore), morphological differentiation and programmed cell death (bacterial apoptosis). Such features are characteristic of more complex developmental systems. Sporulation in *B. subtilis* is therefore a simple developmental system amenable to genetic and biochemical analysis. The process requires 6–8 hr for completion and can be divided into seven stages (Fig. 9.1). At stage 0, the cell senses its environment and makes the decision to initiate sporulation. At stage II an asymmetric cell division has occurred, with the larger cell becoming the mother cell and the smaller cell the forespore. At stage III, the mother cell has completely engulfed the forespore to produce a cell within a cell. A cell type-specific program of gene expression has been established in each compartment at this stage. A series of morphological changes occur between stages IV and VI that lead to the formation of the spore cortex and spore coat. At stage VI, the developing endospore becomes resistant to heat, UV light, and desiccation, and at stage VII the mother cell lyses and releases the mature dormant spore.

FIGURE 9.1 The morphological stages of sporulation in *Bacillus subtilis*. The decision to sporulate has occurred (stages 0 and 1) with two chromosomes (wavy circles) located at opposite poles of the cell. An asymmetric cell division occurs (stage II) with a single chromosome positioned in each compartment. At this stage, SigmaF is activated only in the forespore (smaller) compartment. During engulfment of the forespore (stages II and III), SigmaE becomes active in the mother cell (larger) compartment. SigmaG becomes active on completion of engulfment (stage III). At stage IV, SigmaK is activated in the mother cell and a layer of cortex (stippled ellipse) surrounds the developing spore. Further morphological changes occur during stages IV–VI that include deposition of a coat (dark ellipse) outside the cortex. The mother cell lyses (stage VII), releasing the mature ellipsoidal spore [from Stragier and Losick (1996) with permission, from the *Annual Review of Genetics*, Volume 30, © 1996, by Annual Reviews].

II. THE COMPLETE GENOME SEQUENCE OF *B. SUBTILIS*

A. Genome organization

The complete nucleotide sequence of the *B. subtilis* genome was published in 1997. The circular genome is 4,214 kilobases in size and has an average G + C content of 43.5%. There are 10 regions which have a G + C content significantly lower than average and that correspond to known bacteriophage and bacteriophage-like elements. The origin and terminus of replication are almost perfectly diametrically opposed on the genome. The *B. subtilis* genome displays significant GT skew at third codon positions in common with many other bacteria. The leading strands have an excess of G (9%) and T (4%) over the lagging strands, and the position at which skew reversal occurs corresponds to the positions of the origin and terminus of replication. Approximately 87% of the genome is coding. More than 74% of all open reading frames and 94% of ribosomal genes are transcribed co-directionally with replication.

B. Gene composition

Fifty-three percent of genes are present in single copy. The remainder are present in multigene families, which range in size from those with 2 gene copies (568 genes are duplicated) to the ABC family of transporters that has 77 members. Multigene families present the opportunity for individual member genes to diverge and fulfill different functions and roles within the cell. In addition, individual members can have different regulatory signals so that they can be expressed under different environmental and nutritional conditions. Approximately 220 transcriptional regulators have been identified, including a family of 18 sigma factors (18 different types of promoter), a family of 34 two-component systems, 20 members of the GntR family, 19 members of the LysR family, and 12 members of the Lacl family. It is evident, therefore, that *B. subtilis* has the potential to sense and respond to nutritional and environmental signals in a complex manner. This may be a reflection of the varied habitats in which *B. subtilis* can survive.

C. Gene identity

Approximately 58% of genes can be assigned an identity based either on functional analysis or extensive homology to a gene of known function. Therefore, the function of 42% of genes is unknown. This is a feature

common to all genomes sequenced to date. Twelve percent of the unknown genes have homologs in other organisms. The large number of genes with unknown functions represents a formidable challenge to understanding the metabolism and physiology of *B. subtilis*. It is not clear why such a large number of genes were refractory to discovery by classical genetic analysis. It is probable that among this group are essential genes, redundant genes, and genes which participate in metabolic and physiological processes not yet discovered. Some of these questions will be resolved during the ongoing joint European-Japanese functional analysis project, the objective of which is to examine the expression of all genes of unknown function in *B. subtilis* by systematically inactivating each gene and testing the resultant mutant strain for a wide variety of phenotypes.

The intermediary metabolic pathways and the metabolic potential of a bacterium can be constructed from knowledge of the complete genome sequence. Analysis of this type shows that both the glycolytic and TCA cycles are complete and functional in *B. subtilis*, and the enzymes and regulator genes required for anaerobic growth with glucose as carbon source and nitrate as electron acceptor are also present. Anaerobic growth under these conditions has been experimentally verified.

III. GENETIC METHODOLOGY IN *B. SUBTILIS*

The knowledge of the complete genomic sequence has had a profound effect on research on *B. subtilis*. This is manifest most clearly in the accelerated pace at which research is now done. The information in the complete genomic sequence is enhanced by three additional features: (i) Polymerase chain reaction techniques allow any chromosomal fragment to be rapidly amplified, (ii) the transformation frequency of *B. subtilis* is high, and (iii) there is a sophisticated range of integrating plasmids and transposons available for use in *B. subtilis*.

Integrating plasmids are the predominant and most versatile tool for genetic manipulation of the *B. subtilis* chromosome. The essential features of an integrating plasmid are (i) the inability to replicate autonomously in *B. subtilis*, (ii) the presence of a gene for selecting plasmid establishment in *B. subtilis*, and (iii) a segment of *B. subtilis* chromosomal DNA through which the plasmid can integrate into the chromosome by homologous recombination. There are basically two types of integration events. When the transforming plasmid is circular, integration occurs by a single

crossover event. When the transforming plasmid is linear, and contains two regions of homology with the chromosome, integration occurs by a double-crossover event that results in gene replacement. Incorporating additional genetic functions into the integrating plasmid can extend the repertoire of genetic manipulation. Such functions include reporter genes to generate transcriptional and translational fusions (e.g., β -galactosidase and chloramphenicol acetyl transferase to detect protein accumulation and green fluorescence protein to determine intracellular location), inducible promoters such as P_{spac} (an IPTG-inducible system based on the *lac* operon of *Escherichia coli*), and site-specific recombination functions.

The details of these systems and the mechanisms through which specific genetic manipulations can be achieved using integrating plasmids are beyond the scope of this article. However, it is useful to illustrate the range of genetic analysis that can be performed using integrating plasmids. Any gene can be mutated through either insertional inactivation or deletion. Complementation analysis and the dominance or recessivity of specific mutations can be tested. Genetic loci can be inserted into heterologous sites to test whether they function in *cis* or in *trans*. The phenotype caused by overproduction of a gene product can be assessed by gene amplification. Similarly, amplification of a control region can be used to test for titration of repressors. Large chromosomal fragments can be deleted or inverted. Strains can be constructed with multiple deletions in non-contiguous chromosomal regions. Genes and/or their control regions can be mutated *in vitro* and reinserted into homologous or heterologous sites of the chromosome in single or multiple copy. The expression profile of a gene/operon can be established by generating transcriptional and translational fusions to reporter genes. Regulation at the transcriptional and posttranscriptional levels can be distinguished. Conditional expression of any gene can be effected by placing it under the control of an inducible promoter. This is particularly useful for analysis of essential genes.

IV. GENETIC ANALYSIS OF *B. SUBTILIS*

An objective of bacterial research is to understand how individual processes are regulated and integrated within the cell. Two themes have emerged from the study of how post-exponential phenomena, such as competence development, enzyme production, and sporulation, are regulated: (i) Multiple signals detected by the cell are integrated by a signal

transduction cascade which converges on a central regulator and (ii) the regulation of these processes overlaps so that entering one of these physiological states precludes activation of the other states.

A. Two-component signal transduction systems

It is imperative that bacteria adapt their gene expression and metabolism to the prevailing conditions. Two-component systems comprise a family of proteins, found ubiquitously in bacteria, which sense environmental and nutritional conditions and effect appropriate metabolic and physiological responses. They are generally (but not always) composed of two proteins: a sensor kinase and a response regulator. The kinase detects a parameter(s) of the environment that results in enzyme activation. The active kinase autophosphorylates and then transfers the phosphate to the response regulator. Phosphorylation of the response regulator activates (or alters) its transcriptional activity. Thirty-four two-component systems have been identified in *B. subtilis*, suggesting great versatility and flexibility in its response to changing environmental and nutritional conditions. Three such systems, ComP–ComA, DegS–DegU, and the unusual phosphorelay KinABC–Spo0F–Spo0B–Spo0A, are involved in regulating the post-exponential phase phenomena of competence development, enzyme synthesis, and sporulation, respectively, in *B. subtilis*.

B. Competence development

The regulation of competence development can be divided into three stages: (i) sensing the environmental and nutritional conditions which trigger the process, (ii) the signal transduction pathway that integrates the signals, and (iii) activation of the transcription factor ComK. The composition of the growth medium is an important parameter in competence development. Cells do not become competent in rich medium. In defined medium supplemented with amino acids, competence develops when cells enter the stationary phase of the growth cycle. In defined glucose-minimal medium, cells become competent during exponential growth. Cell density is a second parameter to which competence development responds. This signal is mediated by peptide factors that accumulate in the medium as cells grow to high density. Two such peptides have been identified. Competence stimulating factor (CSF) is a small peptide that is secreted from the cell after signal sequence cleavage. The secreted peptide is further proteolytically processed and a pentapeptide is reimported into

the cell through the oligopeptide transport system. The second peptide, ComX, is secreted from the cell by an unknown mechanism. Accumulation of both these peptides causes an increase in the level of phosphorylated ComA (ComA~P). ComX does this by stimulating the ComP kinase that specifically phosphorylates ComA, whereas CSF is thought to inhibit the activity of a phosphatase which dephosphorylates ComA~P. Phosphorylated ComA then activates expression of *srf*, the surfactin synthetase operon, leading to increased levels of ComS, the next regulator in the signal transduction cascade. ComS is encoded by a small gene (46 codons) located entirely within the much larger *srfA* gene. The reason for this unusual gene organization is not known, but it provides a link between the post-exponential growth phase phenomena of competence development and antibiotic production. ComS destabilizes a ternary protein complex composed of MecA, ClpC, and ComK leading to release of free ComK, which can then function as a transcription factor. ComK also activates its own expression leading to very high levels of the protein, thereby further committing cells to the competent state. The ComK regulon comprises the group of genes and operons encoding the proteins required for binding, fragmentation, and uptake of DNA. The *comF* operon encodes a helicase that is involved in unwinding transforming DNA. The *comG* operon encodes proteins homologous to (i) the pilin protein and proteins involved in pilin assembly, (ii) proteins involved in pullulanase secretion in *Klebsiella pneumoniae*, and (iii) proteins encoded by the *virB* operon of *Agrobacterium tumefaciens* which function to transfer T-DNA from the bacterium to the plant. It is interesting that the transfer of DNA into *B. subtilis* cells shares features with other systems designed to transfer both DNA and proteins across cell walls and membranes.

C. Regulation of enzyme production

Production of extracellular enzymes occurs in response to nutrient limitation, and accumulation is observed when cells enter the stationary phase of the growth cycle. This is approximately the same growth period during which the cells become competent (see Sections I,B and IV,B). Although the regulatory pathways of these two physiological states overlap, it appears that enzyme production and competence development are alternate physiological states. The signals which trigger enzyme production (the nature of these signals is not precisely known) are sensed by the DegS kinase. Activation of the kinase leads to accumulation of phosphorylated DegU (DegU~P). DegU~P is a transcriptional activator which stimulates transcription of

genes encoding the amylases, proteases, and glucanases produced when cells enter the stationary phase of the growth cycle. Two additional regulators, DegQ and DegR, are also required for enzyme production. DegU~P has an additional role in that it inhibits production of ComS, the regulator required for activation of the competence transcription factor ComK. Therefore, accumulation of Deg~P leads to stimulation of enzyme production and inhibition of competence development. In contrast, the non-phosphorylated form of DegU stimulates competence development. Phosphorylation of DegU therefore acts as a switch mechanism allowing cells to become competent (high levels of DegU) or to produce extracellular enzymes (high levels of DegU~P). The equilibrium between the phosphorylated and nonphosphorylated states will depend on the extent to which the kinase (which is responsive to nutritional and environmental conditions) is activated.

D. Regulation of sporulation

1. Initiation of sporulation

The conditions that trigger sporulation include limitation of carbon, nitrogen, and phosphorous and high cell density. These signals, and perhaps others, are sensed and integrated by a signal transduction pathway which converges on the transcriptional regulator Spo0A. The critical parameter in the decision to sporulate is the level of phosphorylated Spo0A, the form of the protein required for transcriptional activation. The nonphosphorylated form of Spo0A has no known transcriptional activity, whereas high Spo0A~P levels are required for initiation of sporulation. The commitment to sporulate is reinforced by a positive autoregulatory loop whereby Spo0A~P activates transcription of the *spo0A* gene. Spo0A is unusual among two-component transcriptional activators in that it is phosphorylated indirectly by a so-called phosphorelay (Fig. 9.2). Spo0F is phosphorylated by sensor kinases in response to nutritional and environmental conditions. The phosphate is then transferred from Spo0F to Spo0A via the Spo0B phosphotransferase. The relative cellular levels of Spo0A and Spo0A~P are the result of competing kinase and phosphatase activities. There are at least three kinases which phosphorylate Spo0F that lead to a buildup of Spo0A~P in the cell. The precise nature of the nutritional and/or environmental signals that activate the kinases is not firmly established. There are also four phosphatases that function to lower the cellular level of Spo0A~P: RapA, RapB, and RapE specifically dephosphorylate Spo0F~P, whereas the Spo0E phosphatase

FIGURE 9.2 The phosphorelay leading to formation of Spo0A~P. A variety of environmental and nutritional conditions (stippled arrows) are sensed by sensor kinases leading to their autophosphorylation. The phosphate group is then transferred from the kinase to Spo0F (to give Spo0F~P). It is subsequently transferred from Spo0F~P to Spo0A (to give Spo0A~P) by the phosphotransferase Spo0B. Phosphate groups can be drained from the phosphorelay at two points: (i) by dephosphorylation of Spo0F~P by any of three response regulator aspartate phosphatases (Rap A/B/E) and (ii) by dephosphorylation of Spo0A~P by Spo0E phosphatase. The phosphatase activities are also responsive to a distinct group of environmental and nutritional conditions (stippled arrows). The competing actions of the kinase and phosphatase activities determine the relative cellular levels of Spo0A and Spo0A~P.

specifically dephosphorylates Spo0A~P. It appears that cell density signals can be detected through these phosphatases by a quorum-sensing mechanism. There is a gene encoding a small peptide juxtaposed to the RapA and RapE phosphatase genes called *phrA* and *phrE*, respectively. The PhrA and PhrE peptides are secreted from the medium, processed, and reimported into the cell. This results in inhibition of Spo0F~P dephosphorylation by RapA and RapE and leads to an increase in the cellular level of Spo0A~P. The genetic evidence indicates that those conditions which favor competence development signal an inhibition of sporulation. For example, the high levels of Com~P that direct competence development also lead to increased levels of RapA, which results in dephosphorylation of Spo0F. This leads to a decrease in cellular levels of Spo0A~P, thereby inhibiting sporulation. The AbrB regulator also provides a link between competence development, enzyme and antibiotic production, and sporulation. The level of AbrB varies throughout the growth cycle to ensure that cells can become competent, produce enzymes, or sporulate but cannot enter all three physiological states at the same time.

2. Regulation of endospore development

a. Activation of SigmaF in the forespore

Asymmetric septum formation in the sporangium is one of the first morphological events of endospore development (Fig. 9.1). At this stage (stage II) there are two complete chromosomes in the sporangium, each having been directed into one of the two compartments by a chromosome partitioning mechanism. When septum formation is complete, the fates of the two cells differ. The smaller compartment becomes the spore and the larger becomes the mother cell. Therefore, it is necessary to establish a separate program of gene expression in each compartment. The first step in this process is activation of expression of the operon encoding the transcription factor SigmaF by high levels of Spo0A~P. This operon is expressed before completion of septum formation and the SigmaF protein is therefore present in both compartments. However, it becomes active only in the forespore compartment. Three additional proteins, SpoIIAA, SpoIIAB, and SpoIIIE, effect asymmetric activation of SigmaF. SpoIIAB is an anti-sigma factor that can bind either to SigmaF (making SigmaF inactive) or to SpoIIAA (allowing SigmaF to be transcriptionally active). The phosphorylation state of SpoIIAA determines whether SpoIIAB binds to SigmaF or to SpoIIAA. When SpoIIAA is phosphorylated, SpoIIAB binds to SigmaF preventing it from engaging in transcription; when SpoIIAA is not phosphorylated, it binds to SpoIIAB and SigmaF can now engage in transcription. The dephosphorylation of SpoIIAA is effected by SpoIIIE, a phosphatase that is located in the asymmetric septum and dephosphorylates SpoIIAA only in the forespore (Fig. 9.3). This is a very clear example of morphological differentiation coupled with regulation of gene expression.

b. Activation of SigmaE in the mother cell

A cell-type-specific pattern of gene expression, mediated by the SigmaE transcription factor, is established in the mother cell after SigmaF has been activated in the forespore (Fig. 9.1). SigmaE protein is also synthesized in the predivisive sporangium and is therefore present in both the forespore and the mother cell compartments. However, it is activated only in the mother cell. SigmaE is activated by cleavage of a small peptide from the amino terminus of the protein. The proteolytic cleavage is effected by SpoIIIGA, a membrane-localized protease (Fig. 9.3). Genetic analysis has revealed that SigmaF must be activated in the forespore before SigmaE can be activated in the mother cell. The basis of this requirement is that

FIGURE 9.3. Crisscross regulation of compartmental gene expression during sporulation. Transcriptional dependency is indicated by thin arrows: transcription of both the sigmaE- and sigmaF- encoding genes requires SigmaA, SigmaH, and Spo0A~P. The formation of the septum (shaded rectangle) between the forespore and mother cell compartments is also dependent on these three transcription factors. SigmaF is required for transcription of the sigmaG-encoding gene in the forespore and SigmaG positively autoregulates its own expression (arrowed circle). Likewise, SigmaE is required for transcription of the sigmaK-encoding gene, which also positively regulates its own expression. A second level of control operates at the level of the activities of these factors (thick arrows). The activity of SigmaF in the forespore is dependent on septum formation and the septum-linked SpoIIIE protein. The activity of SigmaE is dependent on the activity of SigmaF through the septum-linked SpoIIIGA and SpoIIR proteins. The activity of SigmaG is dependent on the activities of SigmaE in the mother cell and the activity of SpoIIIA, whereas the activity of SigmaK is dependent on the activity of SigmaG in the forespore and the activities of SpoIVF and SpoIVB [from Stragier and Losick (1996) with permission, from the *Annual Review of Genetics*, Volume 30, © 1996, by Annual Reviews].

SigmaF is required to produce SpoIIR in the forespore (Fig. 9.3). SpoIIR is then secreted from the forespore into the intercompartmental space between forespore and mother cell where it binds to, and activates, the membrane-localized protease SpoIIIGA. This protease then activates SigmaE, which effects the mother cell-specific program of gene expression.

c. Activation of SigmaG and SigmaK in the forespore and mother cell, respectively

Separate programs of gene expression are first established in the two compartments by activation of SigmaE and SigmaF. These sigma factors are then replaced by two new compartment-specific sigma factors, SigmaG in the forespore and SigmaK in the mother cell. Production of the SigmaE protein is directed by the mother cell-specific SigmaF, whereas production of SigmaG is directed by the forespore-specific SigmaF. However, activation of SigmaG and SigmaK requires a signal from the other compartment (Fig. 9.3). Activation of SigmaG in the forespore requires gene products encoded by the *spoIIIA* operon which is transcribed by SigmaE in the mother cell. Activation of SigmaK in the mother cell is similar to activation of SigmaE. SigmaK must be proteolytically processed to become active. The protease is produced in the mother cell. However, the forespore produces a product (under SigmaG control) which is secreted into the space between the forespore and mother cell that is required for activation of the protease in the mother cell.

d. Features of the regulation of endospore formation

The establishment of temporal and cell-type-specific programs of gene expression in the forespore and mother cell compartments of the sporangium displays many interesting features. Activation of both SigmaE and SigmaF is coupled to the morphological event of asymmetric septum formation by locating SpoIIIE and SpoIIIGA in the septum. Temporal regulation of gene expression is effected by sequential activation of sigma factors. The timing of sigma factor activation and the coordination of gene expression in the forespore and mother-cell compartments are controlled by so-called crisscross regulation (Fig. 9.3). Activation of SigmaF in the forespore is required before SigmaE can be activated in the mother cell; SigmaE must be activated in the mother cell before SigmaG can be activated in the forespore, and SigmaG must be activated in the forespore before SigmaK can be activated in the mother cell (Fig. 9.3). Both SigmaE and SigmaK are activated in the mother cell by two similar (but not identical) signal transduction systems. In both cases, a signal is produced and secreted from the forespore to effect sigma factor activation in the mother cell.

V. CONCLUSION

Bacillus subtilis is a very useful model organism for bacterial research. The complete genome sequence is

known, it is amenable to genetic manipulation, and it exhibits many fundamental biological processes. Whole bacterial genomes can be sequenced with relative ease. However, only a small number of the bacteria are amenable to genetic manipulation. Therefore, the metabolic and physiological capabilities of these bacteria will have to be deduced from knowledge of their gene content coupled with research performed in model organisms such as *B. subtilis*. The large number of genes to which we cannot assign a function suggests that there is still much to be discovered in *B. subtilis*. It is likely, therefore, that *B. subtilis* will remain a primary focus of bacterial research.

Bacteriophages

Hans-Wolfgang Ackermann

Laval University

GLOSSARY

bacteriophage Virus that replicates in a bacterium; literally “eater of bacteria”.

capsid Protein coat surrounding the nucleic acid of a virus.

envelope Lipoprotein membrane surrounding a virus capsid.

genome Complete set of genes in a virus or a cell; in viruses, it consists of either DNA or RNA.

host range Number and nature of organisms in which a virus or group of viruses replicate.

integrase Viral enzyme mediating the integration of viral DNA into host DNA.

prokaryote Type of cell whose DNA is not enclosed in a membrane.

restriction endonuclease Enzyme that recognizes a specific base sequence in double-stranded DNA and cuts the DNA strand at this site.

superinfection Infection of a virus-infected host by a second virus.

virion Complete infectious virus particle.

Bacteriophages, or “phages”, are viruses of prokaryotes including eubacteria and archaeobacteria. They were discovered and described twice, first in 1915 by the British pathologist Frederick William Twort and then in 1917 by the Canadian bacteriologist Félix Hubert d’Herelle working at the Pasteur Institute of Paris. With about 5150 isolates of known morphology, phages constitute the largest of all virus

groups. Phages are tailed, cubic, filamentous, or pleomorphic and contain single-stranded or double-stranded DNA or RNA. They are classified into 13 families. Tailed phages are far more numerous than other types, are enormously diversified, and seem to be the oldest of all phage groups.

Bacteriophages occur in over 140 bacterial genera and many different habitats. Infection results in phage multiplication or the establishment of lysogenic or carrier states. Bacterial genes may be transmitted in the process. Some phages (e.g., T4, T7, λ , MS2, fd, and ϕ X174) are famous experimental models. Phage research has led to major advances in virology, genetics, and molecular biology (concepts of lysogeny, provirus, induction, transduction, eclipse; DNA and RNA as carriers of genetic information; discovery of restriction endonucleases). Phages are used in phage typing and genetic engineering, but the high hopes set on phage therapy have generally been disappointed. In destroying valuable bacterial cultures, some phages are nuisances in the fermentation industry.

I. ISOLATION AND IDENTIFICATION OF PHAGES

A. Propagation and maintenance

1. Propagation

On solid media, phages produce clear, lysed areas in bacterial lawns or, if sufficiently diluted, small holes

called "plaques," each of them corresponding to a single viable phage. In liquid media, phages sometimes cause complete clearing of bacterial cultures. Phages are grown on young bacteria in their logarithmic phase of growth, usually in conditions that are optimal for their host. Some phages require divalent cations (Ca^{2+} , Mg^{2+}) or other cofactors. Phages are propagated by three types of techniques: (i) in liquid media inoculated with host bacteria; (ii) on agar surfaces with a monolayer of bacteria; and (iii) in agar double layers consisting of normal bottom agar covered with a mixture of soft agar (0.3–0.9%), phages, and bacteria. Phages are harvested after a suitable incubation time, generally 3 h for liquid cultures and 18 h for solid media. Phages from agar cultures are extracted with buffer or nutrient broth. Phage suspensions, or lysates, are sterilized, best by filtration through membrane filters (0.45 μm pore size) and then titrated. Sterilization by chloroform or other chemicals is of questionable value.

2. Storage

No single technique is suitable for all phages. Many phages can be kept as lysates at $+4^\circ\text{C}$ or in lyophile, but others are quickly inactivated under these conditions. Lysates should be kept without additives such as thymol or chloroform. The best procedure seems to be preservation at -70°C in 50% glycerol. Phages may also be preserved in liquid nitrogen, by drying on filter paper, and, in the case of endospore-forming bacteria, by trapping phage genomes in spores. Ideally, any phage should be preserved by several techniques.

B. Isolation of phages

1. Isolation from nature

All samples must be liquid. Soil and other solid material are homogenized and suspended in an appropriate medium. Solids and bacteria are removed, usually by filtration preceded or not by centrifugation. Very rich samples can be assayed directly on indicator bacteria. In most cases, phages must be enriched by incubating the sample in a liquid medium inoculated with indicator bacteria. The culture is then filtered and titrated and phages are purified by repeated cloning of single plaques. Large samples must be concentrated before enrichment. This is done by centrifugation, filter adsorption and elution, flocculation, or precipitation by polyethylene glycol 6000. Adsorption–elution techniques may involve strongly acidic or alkaline conditions that inactivate phages.

2. Isolation from lysogenic bacteria

Many bacteria produce phages spontaneously. These phages may be detected by testing culture filtrates on

indicator bacteria. It is generally preferable to induce phage production by mitomycin C, ultraviolet (UV) light, or other agents. A suspension of growing bacteria is exposed to the agent (e.g., 1 $\mu\text{g}/\text{ml}$ of mitomycin C for 10 min or UV light for 1 min), incubated again, and then filtered. After mitomycin C induction, the bacteria should be separated from the agent by centrifugation and transferred into a fresh medium. Bacteriocins (see Section II.C), which are a source of error, are easily identified because they cannot be propagated and do not produce plaques when diluted.

C. Concentration and purification

Small samples of $<100\text{ ml}$ are usually concentrated by ultracentrifugation (about 60 000g in swinging-bucket rotors), followed by several washes in buffer. Fixed-angle rotors allow considerable reduction of the g force because large phages sediment at as little as 10 000g for 1 h. Further purification may be achieved by centrifugation in a CsCl or sucrose density gradient. Large samples raise problems of contamination, aeration, and foaming. Preparation schedules are often complex: (a) pretreatment by low-speed centrifugation and/or filtration; (b) concentration, mostly by precipitation with polyethylene glycol; and (c) final purification in a density gradient or by ultracentrifugation.

D. Identification

Phase identification relies greatly on the observation that most phages are specific for their host genus; however, enterobacteria, in which polyvalent phages are common, are considered in this context as a single "genus." Phages are first examined in the electron microscope. This usually provides the family diagnosis and often indicates relationships on the species level. If no phages are known for a given host genus or only phages of different morphology, the new isolate may be considered as a new phage. If the same host genus has phages of identical morphology, they must be compared to the isolate by DNA–DNA hybridization and/or serology. Further identification may be achieved by determining restriction endonuclease cleavage patterns or constitutive proteins.

II. PHAGE TAXONOMY

A. General

D'Herelle thought that there was only one phage with many races, the *Bacteriophageum intestinale*. Early attempts at classification by serology, host range, and inactivation tests showed that phages were highly

diversified, but these attempts proved premature. Modern taxonomy started in 1962 when a system of viruses based on the properties of the virion and its nucleic acid was introduced by Lwoff, Horne, and Tournier. In 1967, phages were grouped into six basic types on the basis of morphology and nature of nucleic acid. Other types were later established, and this process is likely to continue if more archaeobacteria and other "unusual" microbes are investigated for the presence of phages. The International Committee on Taxonomy of Viruses presently recognizes one order, 13 families, and 31 genera in phages. Their morphology is illustrated in Fig. 10.1 and their basic characteristics and hosts are listed in Tables 10.1–10.5. The most important family criteria are type of nucleic acid, particle shape, and presence or absence of an envelope. As in other viruses, family names end in *-viridae* and genus names in *-virus*. Species are designated by the vernacular names of their best-known (or only) members (e.g., T4 or λ).

B. Phage families and genera

1. Tailed phages

With approximately 4950 observations, tailed phages comprise 96% of phages and are the largest virus group known. They contain a single molecule of dsDNA and are characterized by a tubular protein

tail, a specialized structure for the transfer of phage DNA into host bacteria. Tailed phages have recently been given order rank and the name *Caudovirales*. They fall into three families:

1. Myoviridae: phages with long complex tails consisting of a core and a contractile sheath (25% of tailed phages, six genera named after phages T4, P1, P2, Mu, SPO1, and ΦH);
2. Siphoviridae: phages with long noncontractile, more or less flexible tails (61%, six genera named after phages λ, T1, T5, L1, c2, ψM); and

3. Podoviridae: phages with short tails (15%, three genera named after T7, P22, and φ29).

Classification of tailed phages into genera is still in its infancy. Phage capsids, usually named heads, are icosahedra or derivatives thereof. Capsomers are rarely visible. Elongated heads are relatively rare but occur in all three families. Heads and tails vary enormously in size and may have facultative structures such as head or tail fibers, collars, base plates, or terminal spikes (Fig. 10.2). The DNA is coiled inside the head. Its composition generally reflects that of the

host bacterium, but it may contain unusual bases such as 5-hydroxymethylcytosine. Genetic maps are complex and include 271 genes in phage T4 (possibly more in larger phages). Genes for related functions cluster together. Up to 40 structural proteins have been found in some phages (T4). Lipids are generally absent, but have been reported in a few exceptional cases. Response to inactivating agents is variable and no generalization is possible here. Despite the absence of lipids, about one-third of tailed phages are chloroform-sensitive, making chloroform use in phage isolation a dangerous procedure. Most properties of tailed phages appear as individual or species characteristics. Accordingly, genera have not yet been established, but about 250 species are currently recognizable,

mostly on the basis of morphology, DNA–DNA hybridization, and serology.

2. Cubic, filamentous, and pleomorphic phages

This group includes 10 small phage families that correspond to approximately 4% of phages, differ greatly in nucleic acid nature and particle structure, and sometimes have a single member. Host ranges are mostly narrow (Table 10.4). Capsids with cubic symmetry are, with one exception, icosahedra or related bodies. Filamentous phages have, according to present knowledge, helical symmetry. Particles may or may not be enveloped. As in other viruses, the

(1985). *Les virus des bactéries*. In "Virlogie médicale" (J. Maurin, ed.), p. 200. With permission of Flammarion Médecine-Sciences, Paris.]

presence of lipids is accompanied by low buoyant density and high sensitivity to chloroform and ether.

a. Cubic DNA phages

i. Microviridae The genus *Microvirus* includes the phage ϕ X174 and related phages of enterobacteria and is characterized by large capsomers. Similar phages occur in so taxonomically distinct bacteria as *Bdellovibrio*, *Chlamydia*, and *Spiroplasma*.

ii. Corticoviridae The only certain member of the family Corticoviridae is a maritime phage, PM2. Its

capsid consists of two protein shells and a lipid bilayer sandwiched in between. Two similar, little-known phages were isolated from seawater.

iii. Tectiviridae Phages are characterized by a double capsid and a unique mode of infection. The outer capsid, which is rigid and apparently proteinic, surrounds a thick, flexible lipoprotein membrane. Upon adsorption to bacteria or chloroform treatment, this inner coat becomes a tail-like tube of about 60 nm in length, obviously a nucleic acid ejection device. Tectiviruses of bacilli have apical spikes. Despite their small number, tectiviruses are found in widely different bacteria.

b. Cubic RNA phages

i. Leviviridae Leviviruses resemble enteroviruses and have no morphological features. Most of them are plasmid-specific coliphages that adsorb to F or sex pili and have been divided, by serology and other criteria, into two genera. Several not yet classified leviviruses are specific for other plasmid types (C, H, M, etc.) or occur outside of the enterobacteria family.

ii. Cystoviridae The single officially recognized member of the family Cystoviridae is unique in several ways. It is the only phage to contain dsRNA and RNA polymerase. The RNA is multipartite and consists of three molecules.

c. Filamentous phages

i. Inoviridae The Inoviridae family includes two genera with very different host ranges and similarities in replication and morphogenesis that seem to derive from the single-stranded nature of phage DNA rather than a common origin of these phages. Despite the absence of lipids, viruses are chloroform-sensitive. The *Inovirus* genus includes 42 phages that are long, rigid, or flexible filaments of variable length. They are restricted to a few related Gram-negative bacteria, sensitive to sonication, and resistant to heat. Many of them are plasmid-specific. The *Plectrovirus* genus includes 15 isolates. Phages are short, straight rods and occur in mycoplasmas only.

ii. Lipothrixviridae This family includes four viruses of the archaeobacterial genus *Thermoproteus*. Particles are characterized by the combination of a lipoprotein envelope and rodlike shape.

iii. Rudiviridae This family includes two viruses of different length, isolated from the archaeobacteria *Acidianus*, *Sulfolobus*, and *Thermoproteus*. Particles are straight rods without envelopes and closely resemble the tobacco mosaic virus.

d. Pleomorphic phages

i. Plasmaviridae Only one certain member is known, *Acholeplasma* virus MVL2 or L2. It contains dsDNA, has no capsid, and may be called a nucleoprotein condensation with a lipoprotein envelope. Four similar isolates are known, but one them has been described as containing single-stranded DNA and their taxonomic status is uncertain.

ii. Fuselloviridae This family has only one certain member, SSV1, which is produced upon induction by the archaeobacterium *Sulfolobus shibatae*. Particles are lemon-shaped with short spikes at one end. The coat consists of two hydrophobic proteins and host lipids and is disrupted by chloroform. SSV1 has not been propagated for absence of a suitable host. It persists in bacterial cells as a plasmid and as an integrated prophage (see Section IV.B.1). Possibly related spindle- or droplet-shaped viruses have been found in *Acidianus* and *Sulfolobus*.

C. Plasmids, episomes, and bacteriocins

Plasmids are extrachromosomal genetic elements that consist of circular or linear dsDNA and replicate independently of the host chromosome. Certain prophages behave as plasmids, but phages and plasmids are sharply differentiated: contrary to plasmids, phages have a coat and genomes of uniform size, occur free in nature, and generally lyse their hosts. The term *episome* designates both plasmids and prophages that can integrate reversibly into host DNA. Bacteriocins are antibacterial agents that are produced by bacteria, require specific receptors, and kill other bacteria. High-molecular weight or "particulate" bacteriocins are defective phages (e.g., contractile or non-contractile tails without heads). Low-molecular weight or "true" bacteriocins are a mixed group of entities, including enzymes and phage tail spikes.

D. Origin and evolution of Bacteriophages

Phages are probably polyphyletic in nature and originated at different times. This is indicated by seemingly unbridgeable fundamental differences between most phage families and by their host ranges. Phages may have derived from cell constituents that acquired a coat and became independent (e.g., leviviruses from messenger RNA (mRNA) and filamentous inoviruses from plasmids). Tailed phages are obviously phylogenetically related and may be the oldest phage group of all. Their occurrence in eubacteria and archaeobacteria suggests that they appeared before their hosts diverged, thus at least 3 billion years ago. Phage

groups linked to aerobic bacteria may have emerged at the same time or after the atmosphere became oxygenated by the activity of cyanobacteria. In some cases, nature repeated itself. Convergent evolution is evident in the pseudo-tails of tectiviruses and perhaps in the general resemblance of *Inovirus* and *Plectrovirus* phages.

Microviruses, tectiviruses, and leviviruses show little or no morphological differentiation, possibly because of constraints imposed by capsid size or of the relatively young geological age of these phages. Inoviruses differentiated by elongation. By contrast, tailed phages are extremely diversified and must have an eventful evolutionary history. In terms of structural simplicity and present-day frequency, the archetypal tailed phage from which the other types evolved is a *Siphovirus* with an isometric head. The diversification of tailed phages is attributed to point mutation and uniparental reproduction, which are found in all viruses, and two principal factors: modular evolution by exchange of genes or gene blocks, and the frequency of lysogeny (see Section IV.B.1), which perpetuates prophages and makes them available for recombination with superinfecting phages. Other avenues are gene rearrangement (deletions, duplications, inversions, and transpositions) and recombination with plasmids or the host genome. On the other hand, morphological properties may be highly conserved and some phages appear as living fossils, indicating phylogenetic relationships of their hosts.

III. PHAGE OCCURRENCE AND ECOLOGY

A. Distribution of phages in bacteria

Phages have been found in over 140 bacterial genera distributed all over the bacterial world: in aerobes and anaerobes, actinomycetes, archaeobacteria, cyanobacteria and other phototrophs, endospore formers, appendaged, budding, gliding, and sheathed bacteria, spirochetes, mycoplasmas, and chlamydias (Table 10.4). Phage-like particles of the podovirus type have even been found in endosymbionts of paramecia. However, tailed phages reported in cultures of green algae and filamentous fungi are probably contaminants.

Most phages have been found in a few bacterial groups: enterobacteria (approximately 900 phages), bacilli, clostridia, lactococci, pseudomonads, staphylococci, and streptococci. This largely reflects the availability and ease of cultivation of these bacteria and the amount of work invested. About half of phages have been found in cultures of lysogenic bacteria. Tailed phages predominate everywhere except

in mycoplasmas. In archaeobacteria, they have been found in halobacteria and methanogens, but not yet in extreme thermophiles. Siphoviridae are particularly frequent in actinomycetes, coryneforms, lactococci, and streptococci. Myoviruses and podoviruses are relatively frequent in enterobacteria, pseudomonads, bacilli, and clostridia. There must be phylogenetic reasons for this particular distribution.

B. Phage ecology

1. Habitats

Phages have essentially the same habitats as their hosts; indeed, their most important habitat is the lysogenic bacterium because it protects prophages from the environment and frees them from the need to find new bacteria for propagation. In nature, phages occur in an extraordinary variety of habitats ranging from Icelandic solfataras to fish sauce, fetal calf serum, and cooling towers of thermal power stations. They are found on the surfaces and in normal and pathological products of humans and animals, on plants, and in food, soil, air, and water, especially sewage. Body cavities with large bacterial populations, such as intestines and rumen, are extremely rich in phages. According to their habitat, phages may be acido-, alkali-, halo-, psychro-, or thermophilic. These properties are not linked to particular phage groups but, rather, appear as individual adaptations. Psychrophilic phages are often temperature-sensitive and occur frequently in spoiled, refrigerated meat or fish.

2. Geographical distribution

Except for phages from extreme environments, phage species generally seem to be distributed throughout the whole earth. This is suggested by: (a) electron microscopical observations of rare and characteristic phage morphotypes in different countries; and (b) worldwide distribution of certain lactococcal phage species in dairy plants and of RNA coliphages in sewage. Unfortunately, most data are from developed countries.

3. Frequency of phages in nature

Sizes of phage populations are difficult to estimate because plaque assays and enrichment and (most) concentration techniques depend on bacterial hosts; they therefore only detect phages for specific bacteria and environmental conditions. Consequently, phage titers vary considerably—for example, for coliphages between 0 and 10^9 per gram in human feces and

between 0 and 10^7 per milliliter in domestic sewage. Titters of actinophages in soil vary between 0 and 10^5 per gram. Purely electron microscopic phage counts, which do not allow phage identification, indicate that total phage titers are between 10^4 and 10^7 per milliliter in seawater and may attain 10^{10} per milliliter in sewage and 10^9 per milliliter in the rumen.

4. Persistence of phages in the environment

Phage survival in nature is frequently studied with the aim of using phages as indicators of contamination. The principal experimental models are cubic RNA phages (MS2, f2) because of their resemblance to enteroviruses, other coliphages (ϕ X174, T4), and cyanophages. The indicator value of phages has not been conclusively proven and still lacks a solid statistical basis, but considerable data on phage ecology have been obtained. Phages appear as parts of complex ecosystems including various competing bacteria. Their numbers are affected by factors governing bacterial growth, notably nutrient supply and, in cyanobacteria, sunlight. The lowest bacterial concentration compatible with phage multiplication seems to be 10^4 cells/ml. In addition, phage counts are affected by association of phages with solids and colloids (e.g., clay), presence of organic matter, concentration and type of ions, pH, temperature, UV and visible light, the type of water (e.g., seawater), and nature and phage sensitivity of bacteria. Finally, phage titers depend on intrinsic phage properties such as burst size (see Section IV.A.4) and host range. No generalization is possible and each phage seems to have its own ecology.

IV. PHAGE PHYSIOLOGY

A. The lytic cycle

The lytic cycle, also called vegetative or productive, results in the production of new phages. Phages undergoing lytic cycles only are virulent. Lytic cycles consist of several steps and show considerable variation according to the type of phage (Table 10.3).

1. Adsorption

Phages encounter bacteria by chance and adsorb to specific receptors, generally located on the cell wall, but also on flagella, pili, capsules, or the plasma membrane. Adsorption sometimes consists of a reversible and an irreversible stage and may require cofactors (see Section I.A.1).

2. Infection

In most phage groups, only the viral nucleic acid enters the host and the shell remains outside. The mechanism of this step is generally poorly understood. In the *Inovirus* genus and in cystovirus $\phi 6$, the capsid penetrates the cell wall but not the plasma membrane. In phages with contractile tails, the cell wall is degraded by phage enzymes located on the tail tip. The sheath then contracts (Fig. 10.2) and the tail core is brought in contact with the plasma membrane.

3. Multiplication

The interval from infection to the release of new phages is called the latent period. It depends largely on the nature and physiological state of the host and varies between 20 min and 30–50 h. After infection, normal bacterial syntheses are shut off or modified. Phage nucleic acid is transcribed into mRNA using host and/or phage RNA polymerases. The RNA of leviviruses acts as mRNA and needs no transcription. In tailed phages, gene expression is largely sequential. Host syntheses are shut off first and structural genes are expressed last. According to present knowledge, replication of phage DNA and RNA is semiconservative, each strand of a double helix acting as a template for the synthesis of a complementary strand. In phages with single-stranded nucleic acid, double-stranded replicative forms are produced. In tailed phages, replication generally starts at fixed sites of the DNA molecule, is bidirectional, and generates giant DNA molecules, or concatemers, which are then cut to fit into phage heads. Translation is generally poorly known in phages. Microviridae, Leviviridae, the *Inovirus* genus, and Fuselloviridae have overlapping genes that are translated in different reading frames, allowing the synthesis of different proteins from the same DNA or RNA segment. Lipids, if present at all, are of variable origin. Phospholipids are specified or regulated by phages and fatty acids seem to derive from the host.

The assembly of new phages is called maturation. Phage constituents assemble spontaneously or with the help of specific enzymes. In most phage families, the nucleic acid enters a preformed capsid; in others, the capsid is constructed around or co-assembled with the nucleic acid. In tailed phages, assembly is a highly regulated process with sequentially acting proteins and separate pathways for heads and tails, which are finally joined together. The envelope of plasmaviruses is acquired by budding, but that of cystovirus $\phi 6$ is of cellular origin. The assembly of tailed phages often results in aberrant particles including

giant or multi-tailed phages and structures consisting of polymerized head or tail protein, called polyheads, polytails, or polysheaths. Inoviruses produce particles of abnormal length. Leviviruses and some tailed phages produce intracellular crystalline inclusion bodies.

4. Release

Phages are liberated by lysis, extrusion, or budding. Lysis occurs in tailed and cubic phages and in the Lipothrixviridae. Bacterial cells are weakened from the inside and burst, liberating some 20–1000 phages (often 50–100). Exceptional burst sizes (up to 20000) have been recorded in leviviruses. Extrusion, with phages being secreted through the membranes of their surviving hosts, is observed in inoviruses and fuselloviruses. Budding is found in plasmaviruses. Cells are not lysed and produce phages for hours. Progeny sizes for budding and extruded phages have been estimated at 130–1000 per cell.

B. The temperate cycle

1. Lysogeny

In phages called temperate, infection results in a special equilibrium between phage and host. The phage genome persists in a latent state in the host cell, replicates more or less in synchrony with it, and may be perpetuated indefinitely in this way. It behaves as a part of the bacterium. If this equilibrium breaks down, either spontaneously or after induction, phages are produced as in a lytic cycle. A bacterium harboring a latent phage genome or prophage is called lysogenic because it has acquired the ability to produce phages. Polylysogenic bacteria may carry up to five different prophages. Defective lysogeny is the perpetuation of temperate phages that are unable to replicate and often consist of single heads or tails.

Most temperate phages are tailed, but some members of the *Inovirus* genus and the Lipothrixviridae, Plasmaviridae, and Fuselloviridae can also lysogenize (Table 10.3). Lysogeny is nearly ubiquitous and occurs in eubacteria, including cyanobacteria, and in archaeobacteria. Its frequency in a given bacterial species varies between 0 and 100% (often approximately 40%) according to the species, induction techniques, and number of indicator strains. Mitomycin C and UV light are the principal inducing agents (see Section I.B.2). Many others are known, notably antitumor agents, carcinogens, and mutagens. They often act by damaging host DNA or inhibiting its synthesis.

The λ type of lysogeny is particularly well understood. After infection, the genome of coliphage λ

forms a circle and some λ proteins are immediately synthesized. They direct the bacterial cell to make a choice between the lytic and the temperate cycle. If a certain λ protein prevails, the λ genome integrates via a cross-over, mediated by an enzyme called "integrase," at a specific site of the host DNA. It is then replicated at every bacterial division and makes the bacterium immune against superinfection by related phages. Spontaneous or induced excision of the λ prophage leads to normal phage replication. Some phages have several integration sites.

In the P1 type of lysogeny, the phage genome, though able to integrate, usually persists as a plasmid, perhaps in association with the plasma membrane. In the Mu type, the infecting DNA does not form circles and integrates at random at any site of the bacterial genome. The core domain of Mu integrase (transposase) resembles retrovirus integrase.

2. Pseudolysogeny and steady-state infections

In pseudolysogenic bacteria, only part of a culture is infected with phages and an equilibrium exists between free phages and noninfected, phage-sensitive bacteria. Phage-free strains can be obtained by simple cloning or by cultivating the bacteria in antiphage serum. In steady-state infections, the whole culture is infected, but cells are not lysed and produce phages continuously (see Section IV.A.4).

3. Transduction and conversion

Transduction is transfer of host DNA by viruses and is normally a rare event. In generalized transduction, fragments of bacterial DNA are packaged by accident into phage heads and transferred to a new bacterium. Any host gene may be transferred and the implicated phages may be virulent or temperate. Specialized transduction is carried out by temperate phages that can integrate into host DNA (e.g., λ). If the phage DNA is not properly excised, bacterial genes adjacent to the prophage site may be packaged into phage heads along with normal genes. The resulting particle has a defective genome and may be nonviable. In conversion, bacteria acquire new properties through lysogenization by normal temperate phages. Conversion is a frequent event, affecting the whole bacterial population that has been lysogenized. The new properties are specified by phage genes and include new antigens, antibiotic resistance, colony characteristics, or toxin production (e.g., of diphtheria or botulinus toxin). They will disappear if the bacterium loses its

prophage. Transduction and conversion are common in tailed phages; conversion to cholera toxin production has recently been found in the *Inovirus* genus.

V. PHAGES IN APPLIED MICROBIOLOGY

A. Therapeutic agents, reagents, and tools

1. Therapy and prophylaxis of infectious diseases

Phage therapy started with high hopes and was strongly advocated by d'Herelle. Phages were, enthusiastically and uncritically, applied in many human and animal diseases and spectacular results were reported as well as failures. When antibiotics became available, phage therapy was practically abandoned. The main reasons were host specificity of phages and rapid appearance of resistant bacteria. However, unbeknownst to the West, phage therapy was widely practiced in the former USSR until 1990 and surprisingly good results were reported in the 1980s from Poland. They suggest that phage therapy is a viable therapeutic alternative in antibiotic-resistant pyogenic infections (wounds, abscesses, furunculosis, osteomyelitis, septicemia). More basic research is needed on, for example, inactivation of phages by body fluids. Phage prophylaxis of infectious diseases was also attempted. Despite encouraging results in cholera prevention, it is of historic interest only. Phage control of plant diseases has not been recommended.

2. Identification and classification of bacteria

Early attempts to use phages for bacterial identification were abandoned because no phage lyses all strains of a bacterial species and no others. A few diagnostic phages are still used as screening agents in specialized laboratories, for example, for rapid identification of *Bacillus anthracis*, members of the genus *Salmonella*, or the biotype E1 of *Vibrio cholerae*. By contrast, phage typing is an important technique in epidemiology. In analogy with the antibiogram, bacteria are tested against a set of phages and subdivided into resistance patterns or phage types. Briefly, a continuous layer of bacteria is created on an agar surface, phage suspensions are deposited on it, and results are read the next day. Phage typing is invaluable for subdividing biochemically and serologically homogeneous bacterial species. Besides international typing schemes for *Salmonella typhi* and *Salmonella paratyphi*

B, there are typing sets for most human, animal, and plant pathogenic bacteria. Because of their host specificity, phages are also valuable tools in bacterial taxonomy. Phage host ranges were a major argument in reclassifying *Pasteurella pestis* as an enterobacterium of the genus *Yersinia*.

3. Genetic engineering

Phages have made many contributions to recombinant DNA technology. Restriction endonucleases were first identified in a phage-host system and the DNA ligase of phage T4 is used to insert foreign DNA into viral or plasmid vectors. In addition, phages have several major applications:

1. Phage λ , derivatives of it, cosmids (hybrids between λ DNA and plasmids), phage P1, and "mini-Mu" phages (derivatives of Mu containing the left and right ends of the Mu genome) are used as cloning vectors. Recombinant DNA (vector plus foreign DNA) is introduced into phage proheads. After completion of phage assembly, it can be injected into bacteria.
2. Filamentous coliphages of the *Inovirus* genus are used for DNA sequencing. Foreign DNA is introduced into the double-stranded replicative form of these phages. The same coliphages are also used to express proteins or peptides at their surface. The technique, called "phage display," is a powerful tool for the selection and cloning of antibody fragments.
3. Phage Mu DNA, able to integrate at random into any gene, is used to create mutations and to displace genes to other locations.

4. Other applications

1. Destruction of unwanted bacteria in bacterial and cell cultures, milk, meat, and freshwater (e.g., of cyanobacteria in "algal blooms").
2. Assay of antivirals, disinfectants, air filters, and aerosol samplers.
3. Detection of fecal pollution in water and of carcinogens, mutagens, and antitumor agents.
4. Detection of *Listeria* bacteria in food using luciferase-marked phages.
5. Tracing of water movements (surface water and aquifers).

B. Phages as pests

In industrial microbiology, phages may destroy valuable starter cultures or disrupt fermentation processes.

Phage interference has been reported in various branches of the fermentation industry, notably in the production of antibiotics, organic solvents, and cheese. In the dairy industry, phage infection is considered as the largest single cause of abnormal fermentations and a great source of economic losses. Phages derive from raw material, plant environment, or phage-carrying starter cultures. They are disseminated mechanically by air and may persist for months in a plant. Phage control is attempted by: (i) preventing contamination by cleanliness, sterilization of raw material, sterile maintenance of starter cultures, and use of phage-free starters; (ii) disinfection by heat, hypochlorites, UV light, and other agents; or (iii) impeding phage development by starter rotation, use of genetically heterogeneous starters, and phage-inhibiting media. A recently developed approach is to construct phage-resistant starters by genetic engineering.

Biocides (Nonpublic health, Nonagricultural antimicrobials)

Mohammad Sondossi

Weber State University

GLOSSARY

biocidal agent An agent that kills all living organisms.

biocide Primarily a chemical substance or composition used to kill microorganisms considered to be undesirable (i.e. pest organisms).

biodegradation A chemical breakdown of a substance into smaller molecules caused by microorganisms or their enzymes.

biodeterioration A physical or chemical alteration of a product, directly or indirectly caused by living organisms, their enzymes, or by-products, thereby making the product less suitable for its intended use.

biostatic agent An agent that inhibits or halts growth and multiplication of organisms. This means that when the agent is removed, the organism resumes growth and multiplication.

deteriogenic organisms The organisms that cause biodeterioration.

minimal inhibitory concentration The concentration of a particular biocide/antimicrobial agent necessary to inhibit the growth of a particular microorganism.

selective toxicity The ability of a chemotherapeutic agent (antibiotic, etc.) to kill or inhibit a microbial pathogen with minimal damage to the host at concentrations used.

The Simplest Definition of a Biocide is evident from the terminology: *bio*, meaning life, and *cide*, referring to killing—an agent that destroys life. Therefore, any word with the

suffix *cide* would be classified under the category of biocides. This broad literal meaning encompasses many other topics in this and other encyclopedias. The terms herbicide and insecticide indeed have biocidal activities. Therefore, the topic biocides has to be defined more narrowly in relation to specific subjects and applications.

Perhaps the most appropriate terminology for this topic drawn from common usage is “industrial biocides.” It should be accepted that scientific terms can acquire new or multiple meanings according to common usage. It is of particular importance that terminologies used are consistent and descriptive of the activity of the agents involved. It is imperative to recognize that the terminology implies a specific use and the language used for labeling biocides may have legal consequences. However, the common usage changes the meaning of the terms and even the perception of the spectrum of their activities. Table 11.1 represents some of the common terms related to the control or suppression of microbial growth. According to the Environmental Protection Agency’s (EPA) Office of Pesticide Programs, antimicrobial pesticide (a term used by the EPA) products contain approximately 300 different active ingredients and are marketed in several formulations: sprays, liquids, concentrated powders, and gases. Currently, more than 8000 antimicrobial pesticide products that are registered with the EPA are sold, constituting an approximately \$1 billion market. The EPA estimates that the total amount of antimicrobial pesticide active ingredients used in 1995 was 3.3 billion

TABLE 11.1 Terminology related to control of microbial growth

Term	Definition	Comments
Microbicide	An agent that kills microbes but not necessarily their spores	Usually a general term
Germicide	An agent that kills pathogens and many non-pathogens but not necessarily their spores	A general term
Bactericide	An agent that kills bacteria but not necessarily bacterial endospores	A general term
Fungicide	An agent that kills fungi (mold and yeast) but not necessarily their spores	A general term
Algicide	An agent that kills algae	A general term
Virucide	An agent that inactivates viruses	A general term
Sporocide	An agent that kills bacterial endospores and fungal spores	Sporocidal action is not to be equated to sporicidal action which results in inhibition of spore germination
Sanitizer	An agent that reduces the microbial contaminants to safe levels as determined by public health requirements	Usually used on inanimate objects and places where no specific pathogens are present or suspected and complete killing of all forms of microorganisms is not necessary
Disinfectant	An agent, usually chemical, commonly used on inanimate objects to destroy pathogenic and harmful organisms but not necessarily their spores	Widely used term, legal definition includes more details (relative to factors of time, temperature, percentage kill, concentration, etc.); may inactivate viruses
Antiseptic	Usually a chemical agent commonly applied to living tissue, skin, or mucous membrane to kill or inhibit microorganisms	Not considered safe for internal use
Preservative	An agent that prevents or preempts biodeterioration and spoilage of a product or material under storage conditions	A chemical or physical agent or process resulting in the act of preservation
Chemical sterilizer	A chemical agent that destroys all forms of life, including spores, and inactivates viruses	Sterilization is an absolute term and there are no degrees of sterilization
Bacteriostatic agent	An agent that inhibits growth and multiplication of bacteria but does not kill them	If the bacteriostatic agent is removed bacterial growth may resume
Fungistatic agent	An agent that inhibits growth and multiplication of fungi but does not kill them	If the fungistatic agent is removed fungal growth may resume
Antimicrobial pesticide	Substance or mixture of substances used to destroy or suppress the growth of undesirable (pest) microorganisms on inanimate objects and surfaces	This is the terminology used by the EPA and it encompasses all the antimicrobial agents fitting the definition under public health and nonpublic health categories
Antibiotic	A substance, usually produced by microorganisms, which in low concentrations inhibits the growth or kills disease-causing microorganisms	Synthetic and semisynthetic antibiotics are also available, usually used in treatment of disease; has selective toxicity

lbs, accounting for 75% of all pesticides' active ingredients used. Antimicrobial pesticides, from a regulatory standpoint, are divided into public health products and nonpublic health products. The latter products are used to control microorganisms which cause spoilage, deterioration, or fouling of materials. Industrial biocides are classified under this category. They are chemical compositions used to control and prevent microbial biodeterioration and contamination of industrial/commercial material, systems, and products and/or to improve the efficiency of operation. The application of industrial biocides varies greatly depending on major use categories. Although biocides used in the preservation of cosmetics and personal care products are relevant to this article, they

will not be discussed. The emphasis will be on non-public health-related topics. In the United States, cosmetics and toiletries are regulated under the Federal Food, Drug, and Cosmetic Act.

I. HISTORICAL PERSPECTIVE

Current uses of biocides are aimed at the inhibition and control of undesirable microorganisms based on their antimicrobial action and the microbes' potential roles in biodeterioration, spoilage, and disease. However, even before the discovery of the microbial world by Antoni van Leeuwenhoek in 1674, many practices were used to preserve material, food, and

animal and human bodies (mummification). Although early methods were effective, the scientific foundation of these practices was not understood until almost two centuries after van Leeuwenhoek's discovery. Drying and salting fish and meat was one of the earliest food preservation techniques developed. In cold climates, food could also be buried in snow or underground. An early version of surface sterilization was the practice of passing metal objects through fire to clean them. One of the first documented cases of chemical sanitation was practiced as early as 450 BC in the Persian Empire, where boiled water was stored in copper and silver containers. This allowed for a portable water supply that helped the Persian army in many military conquests. Medical applications of chemical sanitation include the use of mercuric chloride as a wound dressing by Arab physicians in the Middle Ages, the use of bleaching powder as a disinfectant by Alcock in 1827, the use of iodine by Davies in 1839, the use of chlorinated water for hand washing in hospitals by Semmelweis in the 1840s, and the use of phenol on surgical wounds by Lister in the 1860s.

It was not until after the mid-nineteenth century that quantitative and comparative antimicrobial efficacies of some compounds were established. For example, in 1875 Bucholtz determined the minimal inhibitory concentrations of phenol, creosote, salicylic acid, and benzoic acid against bacterial growth. These and other findings were followed by the introduction of hydrogen peroxide as a disinfectant by Traugott in 1893 and chlorine-releasing compounds in 1915 by Dakin. It is obvious that most of these findings and their applications were in the areas of medicine and public health. Here, the description of biocides is not in the context of the general definition based on antimicrobial activity but instead covers applications in more specific areas dealing with biodeterioration. The latter term has been in use for the past 30 years and is basically not present in most dictionaries, traditional printed material, or even recent electronic media. Hueck (1968) defined biodeterioration as any undesirable change in the properties of a material used by humans caused by the vital activities of organisms in which the material is any form of matter, with the exception of living organisms. The term biodeterioration is distinguished from biodegradation in having a more negative or harmful connotation. Where the material is known to be at risk, preventative measures can be taken. These measures could be based on many physical and chemical parameters affecting microbial growth and include the use of biocides. It should be mentioned that the term biocide is also a new term introduced in the past few decades. The range of materials used by man has changed

dramatically in comparison to days when raw materials were used with minimal processing. Currently, complex and heavily processed materials, composites, and synthetic and semisynthetic materials are everywhere. Complex man-made environments and the materials used, combined with a wide range of biotic and abiotic parameters, provide abundant and ideal environments for the growth of microorganisms. The total cost of losses due to biodeterioration and spoilage is approximately \$100 billion per year. When the costs of replacement of deteriorated material, remedial measures, and lost productivity are considered, the importance of preventative measures and the role of biocides is clear.

II. CURRENT APPLICATIONS

There are many arbitrary categories of biocide applications in published articles and reference books. They have been grouped from an application aspect, with some differences. It should be noted that the use of a particular biocide is not restricted to any one group and may be used in different areas. One such summary of application categories could be assembled from articles, reviews, and reference materials as presented in Table 11.2.

Another grouping based on areas of application is used by regulatory agencies (the EPA and the Food and Drug Administration). These groups can be divided into two categories based on the type of microorganism (pest) against which the biocide (antimicrobial pesticide) is used. First, public health antimicrobials are intended to control infectious microorganisms (to humans) in any inanimate environment. Disinfectants, sterilizers, sanitizers, and antiseptics are included in

TABLE 11.2 Selected application areas of biocides

Human drinking water disinfectants and purifiers	Paper and pulp Metalworking lubricants and hydraulic fluids
Freshwater algicide	Oil field operations
Swimming pools	Fuels
Animal husbandry	Textiles
Animal feed preservatives	Paint and paint film preservation
Food and beverage processing hygiene	Wood preservation
Food preservation	Plastics
Crop protection	Resins
Hospital disinfectants	Polymer emulsion, latex, adhesives, slurries
Hospital and medical antiseptics	Tannery
Pharmaceuticals	Museum specimens
Cosmetics	Construction
Personal care disinfectants	
Process cooling water	

TABLE 11.3 Antimicrobial product use sites and categories under consideration by the EPA^a

Agricultural premises and equipment ^b
Food handling/storage establishment premises and equipment ^b
Commercial, institutional, and industrial premises and equipment
Residential and public access premises ^b
Medical premises and equipment
Human drinking water systems ^b
Materials preservatives ^b
Industrial processes and water systems
Antifouling coatings
Wood preservatives
Swimming pools
Aquatic areas

^aMajor use categories are subdivided further based on exposure scenarios.

^bUse of a biocide product on some sites in this category with direct or indirect food contact will be considered a food use and registration must be supported by data sufficient to support the establishment of a tolerance or exemption from the requirement of a tolerance under the Federal Food, Drug, and Cosmetic Act.

this category. Second, the nonpublic health antimicrobial products are the products used to control growth of microorganisms causing deterioration, spoilage, and fouling of material, including growth of algae and odor-causing bacteria. Human exposure, product chemistry, and toxicology are considered in assigning antimicrobial agents into these main application categories.

In order to meet registration and data requirements, the EPA is currently considering classifying the antimicrobial products into 12 major use categories which are further subdivided based on exposure scenarios. The major categories are shown in Table 11.3.

III. EXAMPLES OF INDUSTRIAL BIOCIDES

Providing a complete list of registered industrial biocides is beyond the scope of this article and is not practically possible for many reasons. For example, in the United States, most states require biocide registration after registration with the EPA. In addition to Canada, European countries, and Japan, many other countries have laws regulating biocide registration and use. Toxicological and environmental impact regulations vary worldwide and are reevaluated constantly. An extensive list of biocides with current and past use in North America and Europe is given in Table 11.4, although some have been discontinued, have use limitations, and may not be registered in some countries. Therefore, for updated information on industrial biocides, contacting biocide manufacturers and regulatory agencies is strongly recommended.

Databases are available that indicate the name and location of the basic manufacturers of compounds as listed by CAS registration number. Most of the regulatory statuses can also be obtained from on-line databases and search engines.

IV. CLASSIFICATION OF BIOCIDES

Classifying industrial biocides based on their chemical structures is not an easy task. Many review articles present group classifications and include a miscellaneous group whose members do not fit in any major class. Table 11.5 is a representation of this type of classification.

Biocides are sometimes also grouped based on their mode of action. This can be organized based on the target region of the microorganism affected by biocide action. Terms and categories such as membrane-active biocides and permeabilizers, cell wall inhibitors, cytotoxic agents (affecting targets in cytoplasm and interfering with metabolism and total cell function), and genotoxic agents (affecting DNA biosynthesis and reacting with DNA) have occasionally been used.

The chemical reactivity of biocides provides another, less frequently used, classification. Terms such as oxidizing, non-oxidizing, and electrophilic biocides have been used to separate industrial biocides into smaller groups. Some have used terms such as chlorine-yielding, bromine-yielding, and formaldehyde-releasing compounds to designate specific groups of biocides based on the active moiety/mechanism of action. It is therefore understandable that, depending on the subject, audience, users, and presenters (regulatory, academic, and industry) of information pertaining to industrial biocides, any of these classifications could be used.

V. EVALUATION

There are numerous methods that have been and can be employed to evaluate biocide efficacy, including a variety of basic microbiological tests, simulation tests in the laboratory, practical tests, and field tests to demonstrate the effectiveness of a biocide. First, it has to be demonstrated that the chemical or preparation being evaluated has antimicrobial activity. In this stage, the spectrum of activity is determined against bacteria (gram-positive, gram-negative, Mycobacteria, etc.), fungi (mold and yeast), and spores (bacterial and fungal) and dose-response relationships are established.

TABLE 11.4 Selected industrial biocides^{a,b}

Active chemical	Applications
6-Acetoxy-2,4-dimethyl- <i>m</i> -dioxane	Metalworking fluids, textile lubricants, polymer emulsions, other aqueous emulsions
Acrolein (acrylaldehyde)	Paper and pulp
Alkenyl (C12–C18)dimethylethyl ammonium bromide	Paper and pulp, process cooling waters
Alkyldimethylbenzyl ammonium chloride	Wood, process cooling waters
Arsenic pentoxide	Wood
1-Aza-3,7-dioxa-5-ethylbicyclo-[3.3.0]octane	Metalworking fluids
1,2-Benzisothiazolin-3-one	Adhesive, latex, paper coatings, aqueous emulsions
Benzyl bromoacetate	Paint raw materials (cellulose and casein)
Benzyl-hemiformals mixture	Adhesives
Bis(1,4-bromoacetoxy)-2-butene	Paper and pulp
5,5-Bis(bromoacetoxymethyl)- <i>m</i> -dioxane	
2,6-Bis(dimethylaminomethyl) cyclohexanone	
1,2-Bis(monobromoacetoxy) ethane	
Bis(tributyltin)oxide	Wood, process cooling water
Bis(trichloromethyl)sulphone	Paper and pulp, process cooling water, adhesives, wet state protection concrete additives
Boric oxide	Wood
Brominated salicylanilides	Water-based latex pains and emulsions, joint cement, PVC plastic, acrylic and PVA water-based paints, polyvinyl acetate latex, adhesives
5,4'-Dibromosalicylanilide	
3,5,6'-Tribromosalicylanilide	
Other brominated salicylanilides	
Bromine-yielding chemicals	Process cooling waters
Sodium bromide, NaBr (must be activated by oxidizing agent, e.g. NaOCl, Cl ₂ , and potassium peroxymono-sulfate)	
1-Bromo-3-chloro-5,5-dimethylhydantoin	
4-Bromoacetoxymethyl- <i>m</i> -dioxolane	Paper and pulp
2-Bromo-4'-hydroxyacetophenone	Pulp and paper mills, paper making chemicals, felt
2-Bromo-2-nitro-1,3-propanediol	Metalworking fluids, textile, Process cooling waters
Bromo-nitrostyrene	Pulp and paper mills, water systems, lignosulphonates
1,1'-(2-Butenylene)bis(3,5,7-triaza-1-azoniaadamantane chloride)	Latex paints, resin emulsions, adhesives, dispersed colors
Chlorethylene bithiocyanate	Water systems, emulsions
Chlorinated levulinic acids	Paper and pulp
Chlorine/chlorine-yielding chemicals:	Process cooling waters
Chlorine (gas), Cl	
NaOCl	
Ca(OCl) ₂ ·4H ₂ O	
Na dichloro- <i>s</i> -triazinetrione/trichloro- <i>s</i> -tri azinetrione	
1-Bromo-3-chloro-5,5-dimethylhydantoin	
1-Bromo-3-chloro-5-methyl-5-ethylhydantoin	
1,3-Dichloro-5,5-dimethylhydantoin	
Chlorine dioxide, ClO ₂	
1-(3-Chloroallyl)-3,5,7-triaza-1-azoniaadamantane chloride + sodium bicarbonate	Adhesives, metalworking fluids, latex paints, textile, emulsions, water-based coating formulations
Chloromethyl butanethiolsulfonate	Paper and pulp
5-Chloro-2-methyl-4-isothiazolin-3-one + 2-methyl-4-isothiazolin-3-one	Wood veneer, cutting fluids and coolants, paste, slimes, cooling towers, paper, and paperboard
<i>p</i> -Chlorophenyl diiodomethyl sulfone	Paint
Chromic oxide	Wood
Coal tar creosote	Wood
Copper naphthenate	Wood
Copper sulfate	Wood
Cupric oxide	Wood
Copper-8-quinolinolate	Wood and wood products, glues and adhesives, paper products
Cresylic acids	Rubbers (synthetic and natural)
Cupric nitrate	Paper and pulp
Dialkyl methylbenzyl ammonium chloride	Paper and pulp, wood, process cooling waters
1,2-Dibromo-2,4-dicyanobutane	Metalworking fluids, aqueous paints, latex emulsions, joint cement adhesive

(Continued overleaf)

TABLE 11.4 (Continued)

Active chemical	Applications
2,2-Dibromo-3-nitrilopropionamide (20, 10, or 5%) in polyethylene glycol	Water cooling towers, pulp and paper mills, metalworking fluids, oil recovery
2,3-Dibromopropionaldehyde	Paper and pulp
2,4-Dichlorobenzyl alcohol	Textile
2,3-Dichloro-1,4-naphthoquinon	Toxic wash of construction material (interior use)
Didecyl dimethyl ammonium chloride	Wood
(2,2'-Dihydroxy-5,5'-dichloro)-diphenyl methane	Textile, cement additive, toxic wash (exterior use)
(2,2'-Dihydroxy-5,5'-dichloro)-diphenyl monosulfide	Textile
Di-iodomethyl- <i>p</i> -tolyl sulfone	Paint
Di-isocyanate	Toxic wash construction material (interior use)
Ditmethyl aminomethyl phenol	Rubbers (synthetic and natural)
Dimethylbenzyl ammonium chloride	Construction toxic wash (exterior and interior use)
4,4-Dimethyloxazoldine + 3,4,4-trimethyloxazoldine	Metalworking fluids, in-can paint
3,5-Dimethyl-tetrahydro-1,3,5-2 <i>H</i> -thiadiazine-2-thion	Leather, paint, glue, casein, starch, paper mill
Diocetyl dimethyl ammonium chloride and ethanol	Cooling water systems
Diquat 1,1-ethylene-2,2-dipyridylium	Construction toxic wash (exterior and interior use)
Disodium cyanodithioimidocarbamate	Paper and pulp, process cooling waters
Disodium ethylenebis(dithiocarbamate)	Paper and pulp, process cooling waters
Dithio-2,2-bis-benzmethylamide	Adhesives
Dithiocarbamates + benzimidazole derivatives	Adhesives, filters, stoppers, groutings, jointing compounds, sealants, putty
Dodecylamine salicylate	Construction toxic wash (exterior and interior use)
Dodecylguanidine hydrochloride, dodecylguanidine hydro-chloride	Paper and pulp, process cooling waters
Fatty acids of quaternary compounds	Textile
Fluorinated sulfonamide	Filters, stoppers, groutings
Formaldehyde	Toxic wash (exterior and interior use)
Glutaraldehyde (1,5-pentanedial)	Metalworking fluids, Process cooling waters
1,2,3,4,5,6-Hexachlorocyclohexane (lindane)	Wood
Hexachloro dimethyl sulfone	Industrial emulsions
Hexahydro-1,3,5-triethyl- <i>s</i> -triazine	Cutting oils, synthetic rubber latexes, adhesives, latex emulsions
Hexahydro-1,3,5- <i>tris</i> (2-hydroxyethyl)- <i>s</i> -triazine	Cutting oils and diluted coolants
Hydrogen peroxide	Process cooling waters
<i>p</i> -Hydroxybenzoic acid esters	Adhesives, starch and gum solutions, inks, polishes, latexes, other emulsions
Ethyl <i>p</i> -hydroxybenzoate	
Methyl <i>p</i> -hydroxybenzoate	
Propyl <i>p</i> -hydroxybenzoate	
Butyl <i>p</i> -hydroxybenzoate	
5-Hydroxymethoxymethyl-1-aza-3,7-dioxabicyclo(3.3.0)octane	Latex paints
5-Hydroxymethyl-L-aza-3,7-dioxabicyclo(3.3.0)octane	
5-Hydroxypoly[methyleneoxy (74% C2, 21% C3, 4% C4, 1% C5)]methyl-L-aza-3,7-dioxabicyclo(3.3.0)octane	
2-[(Hydroxymethyl) amino] ethanol	Paints, resin emulsions, in-can paint
2-[(Hydroxymethyl) amino]-2-methylpropanol	Latex paints, resin emulsions
2-(<i>p</i> -Hydroxyphenyl) glyoxylohydroximoyl chloride	Paper and pulp
2-Hydroxypropyl methanethiol sulphionate	Paper and pulp, paint films
3-Iodo-2-propynyl butyl carbamate	Interior and exterior coatings
3-Methyl-4-chlorophenol	Adhesives, filters, stoppers, groutings
Methyl-2,3-dibromopropionate	Process cooling waters
2,2'-Methylenebis(4-chlorophenol)	Textiles, rubber products, hoser
Methylene bis thiocyanate	Paper slimes, recirculating cooling water systems
<i>N</i> -[alpha-(nitroethyl)benzyl] ethylenediamine	Paper and pulp
<i>N</i> -dimethyl- <i>N'</i> -fluorodichloromethylthio) sulfamide	Construction toxic wash (exterior use)
<i>N</i> -(fluorodichloromethylthio) phthalimide	Construction toxic wash (exterior and interior use), jointing compounds, sealants, putty, plastic products
<i>N</i> -trichloromethylthio-4-cyclohexene-1,2-dicarboximide	Paper and pulp, polyethylene, paint, paste, rubber and rubber-coated products
<i>N</i> -(trichloromethylthio) phthalimide	Nonaqueous paints and caulking compounds

TABLE 11.4 (Continued)

Active chemical	Applications
<i>N</i> -(trimethylthio) phthalimide	Paint film
2-Nitrobutyl bromoacetate	Paper and pulp
4-(2-Nitrobutyl) morpholine + 4,4'-(2-ethyl-2-nitrotrimethylene) dimorpholine	Metalworking fluids, pulp and paper industry, petroleum production, jet fuels
2- <i>n</i> -Octyl-4-isothiazolin-3-one	Latex and oil-based paints, in-can paint preservative, fabrics, wet processing of hides
Organic mercurials	Paints
Organosulfur compound blends	Cooling towers, air washer systems
Organotin, quartemaries and amines	Cooling water systems
10,10'-Oxybisphenoxarsine 5% in a polymeric resin carrier	PVC, polyurethane, other polymeric compositions
10,10'-Oxybisphenoxarsine in various nonvolatile plasticizer carriers	Film and sheeting, extruded plastics, plastisols, molded goods, organosols, fabric coatings, etc.
2,2'-Oxybis-(4,4,6-trimethyl-1,3,2-dioxaborinane)-2,2'-(1-methyltrimethylenedioxy)-bis-(4-methyl-1,3,2-dioxaborinane)	Hydrocarbon fuels, boat and ship fuel and marine storage, home heating fuel
Oxyquinoline	Plastic products
Oxyquinoline sulphate	Plastic products
Ozone	Process cooling waters
Para-chloro-meta-cresol	Metalworking fluids
Para-chloro-meta xylenol	Metalworking fluids
Pentachlorophenol	Wood preservation, adhesives, cement additive, toxic wash (exterior use), rubbers (synthetic and natural)
Pentachlorophenyl laurate	Adhesives, wet state protection concrete additives, plastic products, rubbers (synthetic and natural), textile
Phenoxy fatty acid polyester	Bitumen products, jointing compounds, sealants, putty
Phenyl mercury acetate	Adhesives
Phenyl mercury nonane	Adhesives, wet state protection concrete additives
Phenyl mercury oleate	Adhesives, wet state protection concrete additives
<i>o</i> -Phenylphenol(sodium- <i>o</i> -phenylphenate tetrahydrate)	Protein-based paints, metalworking fluids, polishes, adhesives, gums, latexes, textiles
Polychlorophenates, alcohol, and amines	Cooling towers and evaporative condensers
Polychlorophenates, organosulfurs	Cooling towers
Poly[hydroxyethylene (dimethyliminio)-ethylene (dimethyliminio)]methylene dichloride	Industrial water systems, process cooling waters
Poly[oxyethylene (dimethyliminio)-ethylene (dimethyliminio)]-ethylene dichloride	Cooling water systems, cutting fluids
Potassium dichromate	Wood
Potassium dimethyl thiocarbamate	Metalworking fluids, process cooling water
Potassium <i>N</i> -hydroxymethyl- <i>N</i> -methylthiocarbamate	Water-thinned colloids, emulsion reins, emulsion paints, waxes, cutting oils, adhesives
Potassium <i>N</i> -methylthiocarbamate	Paper and pulp, process cooling waters
Quaternary phosphonium salt + surfactant	Textile
Rosin amine D-pentachlorophenate	Paper, textiles, rope, emulsion systems
Salicylamide	(Cable insulation) jointing compounds, sealants, putty, plastic products
Silver fluoride, silver nitrate	Paper and pulp
Sodium dimethylthiocarbamate	Paper mills, cooling towers, paper and paperboard, cotton fabrics, paste, wood, veneer, cutting oils
Sodium fluoride	Wood
Sodium 2-mercaptobenzothiazole	Adhesives, wet state protection concrete additives, paper mills, cooling towers, paper and paperboard, cotton fabrics, paste, wood, veneer, cutting oil, water-thinned colloids, emulsion reins, emulsion paints, waxes, adhesives, textiles, rug backings
Sodium pentachlorophenate	Paper making, pulp, paper and paper products, leather, hides, drilling muds
Sodium 2-pyridinethiol-1-oxide	Aqueous-based metalworking fluid systems, vinyl, latex emulsions for short-term, in-can inhibition of bacterial growth
1,3,6,8-Tetraazatricyclo[6.2.1.1]dodecane	Paper and pulp
2,4,5,6-Tetrachloroisophthalonitrile	Adhesives, jointing compounds, sealants, putty, plastic products, latex paints

(Continued overleaf)

TABLE 11.4 (Continued)

Active chemical	Applications
2,3,4,6-Tetrachlorophenol	Wood preservation
3,3,4,4-Tetrachlorotetrahydrothiophene-1,1-dioxide	Paper and pulp
Tetrahydro-3,5-dimethyl-2 <i>H</i> -1,3,5-thiadiazine-2-thione and blends	Slimicide for coatings, clay slurries, adhesives, glues, latex emulsions, casein, titanium slurries, cooling towers
2-(4-Thiazolyl)benzimidazole	Paint
2-(Thiocyanomethylthio)benzothiazole	Wood, paint films
Tributyltin acetate	Cement additive, paints
Tributyltin fluoride	Wood, antifouling paint
Tributyltin maleate	Textile
Tributyltin oxide	Construction toxic wash (exterior and interior use), wet state protection concrete additives, antifouling paints, adhesives, wood
Tributyltin oxide + nonionic emulsifier	Construction toxic wash (exterior and interior use), wet state protection concrete additives
Trifluoromethyl thiophthamide	Construction toxic wash (exterior use)
3-(Trimethoxysilyl)-propyl-dimethyloctadecyl ammonium chloride	
Tris(hydroxymethyl) nitromethane	Oil in water emulsions, pulp and paper industry, water treatment, in-can paint
Zinc dimethylditbiocarbamate	Adhesives, cooling water, paper mill, paper and paperboard, textiles
Zinc 2-mercaptobenzothiazole	
Zinc naphthenate	Textile, wood
Zinc 2-pyridinethiol-1-oxide	Aqueous-based metalworking fluids, PVC plastics

^aNot necessarily currently registered and some have been discontinued. This list was collected from many sources, including Sharpell (1980), Allsopp and Allsopp (1983), Bravery (1992), Rossmoore (1995a,b), Lutey (1995), Eagon (1995), McCarthy (1995), Downey (1995), and Leightley (1995).

^bCurrent registration eligibility decision (RED) and fact sheets on biocides can be found on: <http://www.epa.gov/pesticides/reregistration/status.htm>.

TABLE 11.5 Biocides by chemical class^a

Phenols	Alcohols
Organic and inorganic acids: esters and salts	Peroxygens
Aromatic diamidines	Chelating agents
Biguanides	Heavy metals and
organometallic compounds	
Surface-active agents: cationic and anionic agents	Anilides
Aldehydes: formaldehyde, glutaraldehyde, and others	Formaldehyde adducts
Dyes	Isothiazolones
Halogen compounds	Organosulfur compounds
Quinolines and isoquinoline derivatives	Essential oils
	Miscellaneous

^aFrom Hugo and Russell (1992), Rossmoore (1995a), and others.

The nature of antimicrobial activity, biocidal or biostatic, may also be determined. The second stage includes suspension tests to determine MIC, establishing kill curves by plating, capacity tests (several reinoculations), and carrier tests (effects on organisms on the carrier). These may be followed by practical tests that, although done in the laboratory, demonstrate the efficacy under real-life conditions. Third, and most important, is evaluation in the field and under actual use conditions. For the regulatory

agencies and registration purposes the tests should satisfy the label claims for specific applications. There are numerous test methods issued by federal and state governments or government-sanctioned publications, standards societies, and trade organizations as well as test methods developed by biocide manufacturers, users, and testing laboratories to demonstrate efficacy. Among governmental-sanctioned publications are those by the Association of Official Analytical Chemists, the American Public Health Association, and the United States Pharmacopeia. Voluntary consensus standards societies and groups include the American National Standards Institute, the American Society for Testing and Materials, and the International Standards Organization.

VI. MODE OF ACTION

Considering the heterogeneity of chemicals used as biocides, and the fact that they have been considered general cell poisons for a long time, one can understand the lack of detailed information on mode of action of industrial biocides. For most of the biocides, mode of action seems to be a concentration-dependent phenomenon by which individual effects can be

identified and studied. Since biocides will act on organisms in an outside to inside direction, many have classified the target regions based on this directional impact. In other words, the cell wall, cell membrane and membrane-associated components, and the cytoplasmic regions will be sequentially affected by the biocide as it interacts with the intended target organism. Unlike antibiotics that have very specific targets, biocides may have more than one potential target. These could be located at any or all areas of the affected cell. The chemical structure of a biocide determines its affinity to specific targets and is the key to understanding its mode of action. Furthermore, the accumulated effects of sequentially affected regions of the cell may ultimately manifest as antimicrobial activity. Considering the structural and physiological differences of organisms and extrinsic parameters affecting the activity of biocides, the knowledge about mode of action is far from comprehensive. However, it is becoming increasingly evident that biocides indeed have a specific target(s) and cannot be labeled as general cell poisons.

Abnormal morphology of organisms exposed to biocides, studied by light and electron microscopy, has long been considered evidence of damage to the cell wall or its construction process. Lysis of cells due to initiation of autolysis has also been included in this category of mode of action. Early reports classified phenol, formaldehyde, mercurials, alcohols, and some quaternary ammonium compounds in this category. It should be noted that any of these events could also be a consequence of damage(s) exerted on cytoplasmic targets or initiated by trans-membrane signaling events. Since the cell wall composition of microorganisms (e.g., gram-positive and gram-negative bacteria, mycobacteria, fungi, and algae) differs significantly, one biocide may cause damage to the cell wall of one organism and may have no effect on the cell wall of another. Interaction with the cytoplasmic membrane, membrane-bound enzymes, electron transport, and substrate transport systems are the next group to be affected by the action of biocides. Among other biocides, chlorhexidine, 2-bromo-2-nitro-1,3-propanediol, and 1,2-benzisothiazolin-3-one have been reported to affect targets in the cytoplasmic membrane. Some membrane-active biocides may cause leakage of the intracellular material, whereas others have been reported to produce an increased permeability to ions acting as uncouplers of oxidative phosphorylation and inhibitors of active transport. Although there are many early reports that describe the mode of action of certain biocides in terms such as coagulation of cytoplasmic proteins and precipitation of cytoplasmic constituents, there are recent reports of

more specific actions on selective inhibition of cytoplasmic enzymes and reactions with essential biomolecules. These more specific interactions result in inhibition of selected biosynthetic and energy-producing processes in the affected organisms.

Some recent reports describing more specific aspects of industrial biocides' modes of action include the following examples: 2-pyridinethiol-1-oxide has been suggested to act on cell membranes to eliminate important ion gradients used to store energy. In fungi, it eliminates the membrane charge gradient and interferes with nutrient transport. The collapse of delta, the pH component of the proton motive force, affects bacterial cells. It has been suggested that 2-pyridinethiol-1-oxide is not accumulated in cells and is not destroyed during action on cells but rather acts catalytically. 2-Hydroxybiphenyl ethers effectively inhibit fatty acid synthesis *in vivo* and the key enzyme of the fatty acid synthase system *in vitro*. This contradicts early reports on mode of action due to direct disruption of cell membranes. 5-Chloro-2-methyl-4-isothiazolin-3-one has been claimed to have multiple modes of action in the inhibition of microorganisms. These include lethal loss of protein thiols by covalent modification of protein molecules through direct electrophilic attack, generation of secondary electrophiles by disulfide exchange and tautomerization to a thioacyl chloride, and intracellular generation of free radicals as a result of the severe metabolic disruption.

Early studies on the mode of action of 2-bromo-2-nitro-1,3-propanediol using *Escherichia coli*, *Staphylococcus aureus*, and *Pseudomonas aeruginosa* indicated effects on cell membrane integrity and also on aerobic glucose metabolism. The major finding was the inhibition of thiol-containing enzymes such as glyceraldehyde-3-phosphate dehydrogenase. Studies on cysteine and glutathione showed the ability of 2-bromo-2-nitro-1,3-propanediol to oxidize the thiol group to form a disulfide bond and this was postulated as the inhibition mechanism. Later work confirmed this property of 2-bromo-2-nitro-1,3-propanediol, showing that it acted catalytically to oxidize thiol groups under aerobic conditions. In addition, there was evidence that 2-bromo-2-nitro-1,3-propanediol led to the formation of active oxygen species such as superoxide, suggesting interference with the electron transport mechanism within the cell.

There have also been reports which do not directly describe mode of action but rather clarify active moiety(s) involved in mode of action of certain groups of biocides. There are many industrial biocides that are synthesized with formaldehyde as one of the starting materials. The question about the role of formaldehyde in mode of action of formaldehyde-adduct

biocides was not always clearly addressed. Studies with bacterial strains resistant to formaldehyde and formaldehyde-adduct biocides derived separately from sensitive wild types and concurrent development of cross-resistance among all resistant strains established formaldehyde as the active moiety in mechanism of action of many formaldehyde-adduct biocides. Subsequently, it was shown that high levels of resistance were coupled to high levels of formaldehyde dehydrogenase in resistant cells. Although this does not resolve the problem of mode of action of formaldehyde, it consolidates the mechanism of action question and clearly demonstrates the involvement of formaldehyde as the active moiety in mode of action of many formaldehyde-adduct biocides. Table 11.6 shows some of these formaldehyde-adduct industrial biocides. There are many other adducts that are not included, although partial formaldehyde involvement in mode of action has been suggested.

VII. COMBINATION BIOCIDES (MIXTURES AND FORMULATIONS)

Biocides are used in combination for many reasons: (i) to broaden the antimicrobial spectrum; (ii) to minimize physical and chemical incompatibilities; (iii) to minimize toxicity; and (iv) to produce biochemical synergism. In its broadest sense, the subject of interactions among industrial biocides that alter their biological activities would include interactions in the extracellular environment and those within the target organisms. Gathering data on combined modes of action of biocide mixtures is not an easy task. Although many biocide mixtures have been used and are commercially available, a considerable amount of

^aFrom Rossmoore (1995b).

research will be required to define the biochemical nature of these interactions and their physiological effects on microorganisms. A select number of biocide mixtures primarily used in metalworking and hydraulic fluids are listed in Table 11.7. It should be noted that there are many more mixtures with a variety of applications and different active ingredients.

Traditionally, a toxicological interaction has been described as "a condition in which exposure to two or more chemicals results in a quantitatively or qualitatively altered biological response relative to that predicted from the action of a single chemical. Such multiple-chemical exposures may occur simultaneously or sequentially in time and the altered response may be greater or lesser in magnitude" (Murphy, 1980). It has been common practice to classify the quantitative joint action of chemicals including biocides using three general terms:

Addition: when the toxic effect produced by two or more biocides in combination is equivalent to that expected by simple summation of their individual effects.

Antagonism: when the effect of a combination is less than the sum of the individual effects.

Synergism: when the effect of the combination is greater than would be predicted by summation of the individual effects.

For biocides, there must be a quantitatively definable effect for each compound involved. Minimal inhibitory concentrations and other dose-response information could be used to construct a graphic representation (isobologram) to show additive, synergistic, and antagonistic interactions in biocide mixtures. This could easily be applied to combinations of any number of agents. For a combination of more than three agents, no graphic construction is possible; however, the interaction index

could be calculated mathematically to describe additivity, antagonism, and synergism.

Because development costs of new biocides are estimated between \$10 and \$15 million, the introduction of new biocidal compounds to the market is difficult. This cost escalation is due to increasing legislative requirements and concerns regarding environmental impact. Therefore, the use of registered biocides in combinations that yield synergistic activity is an attractive alternative.

There is an extensive range of biocides from which to formulate mixtures, with substantially reduced initial screening costs and possibly an easier registration process if the active ingredients are well known and individually registered for particular end use(s). However, there are concerns regarding the toxicity and environmental impact of biocide mixtures.

VIII. RESTRICTIONS ON USE AND REGULATION

The fundamental requirements for industrial biocides suitable for protection of material in the early days of use were effective and aggressive antimicrobial activities, broad spectrum of activity, stability and persistence, and economical feasibility. With the constant expansion of biocide use and number, there has been increasing concern about their impact on human and environmental health. In approximately the past two decades, regulatory agencies have put in place restrictions for the application and selection of industrial biocides. The new requirements include spectrum of activity and effectiveness according to the category of application, stability relevant to application, very low human toxicity according to required toxicological data, very low environmental impact (ecotoxicity), and economical feasibility of use. This has produced a stream of new regulations.

The EPA registers and regulates antimicrobial pesticides including industrial biocides under the Federal Insecticide, Fungicide and Rodenticide Act (FIFRA). To register an industrial biocide, manufacturers of such products must meet EPA requirements to show that: (i) the product will not cause unreasonable adverse effects on human health and the environment; and (ii) the product labeling and composition comply with requirements of FIFRA. Since 1996, the antimicrobials division within the Office of Pesticide Programs (OPP) has been responsible for all activities related to regulating antimicrobial pesticides. The OPP reviews submitted detailed and specific information on the chemical composition of the product,

efficacy data against specific intended microorganisms, support of directions for use on the label, appropriate labeling for safe and effective use, and extensive toxicological data and hazards associated with the product use.

Title 40 CFR, Part 158, explicitly outlines the data requirements for antimicrobial pesticides. Further amendments are being considered to Part 158. These data requirements are for tiered human health and exposure data requirements for nonfood uses, product chemistry, and toxicology. Explicit tiered testing approaches for environmental fate and effects have been developed for antimicrobials, wood preservatives, antifoulants, and algicides. Specifically, data are required for end-use antimicrobial products, including data on end-use formulation, active ingredient, product chemistry information, residue chemistry, efficacy, toxicity, environmental fate, and ecotoxicity. Data are required to assess acute toxicity, chronic and subchronic toxicity, developmental toxicity, reproductive toxicity, mutagenicity, neurotoxicity, metabolic effects, and immunological effects. Toxicology test requirements are set out in tiers based on general requirements and risk assessment. It should be noted that the EPA may require additional data on a case-by-case basis in order to conduct a risk assessment for the product.

To ensure that biocides meet current scientific and regulatory standards, EPA is reviewing older pesticides, including biocides, under FIFRA. This process is called reregistration and considers human health and ecological effects of pesticides. Biocides registered prior to November 1984 are being processed first. Numerous documents containing information on biocides could be found on EPA web sites.

IX. PROBLEMS ASSOCIATED WITH BIOCIDES USE

It should be kept in mind that biocides are all toxic by definition and most are also corrosive. For decades there have been concerns regarding toxicity issues of biocides, even though biocides must be registered for specific use and require a battery of data submissions which include human and environmental toxicological profiles. Recognition for the need to control risks from biocides has come from scientists in academia, regulatory agencies, and industry, and there is a need for comprehensive information and new data especially on the biocide mixtures and biocide-containing formulations. One of the most important problems based on toxicity concerns is the international

recognition of the registration of biocides. Acceptance of toxicity data, including ecotoxicity of biocides, by the regulatory bodies in different countries has been of great concern to multinational producers of biocides.

In addition to the regulatory concerns associated with biocide use, there are problems beyond the obvious toxicity of biocides that have to be considered. Like antibiotics, when biocides interact with mixed populations of microorganisms they kill all susceptible organisms and promote the selection of resistant populations. The level of resistance may be intrinsic, developed by mutation, or could even be acquired by gene exchange. It should be very clear from the previous discussion that the ultimate result of biocide use is selection of resistant populations. Although resistance is a relative term, a resistant organism is one that is not affected by biocide concentrations used to control microorganisms regularly found in a system. There are many review articles on the development of resistance to antimicrobial agents (including antibiotics). These reviews and numerous other research articles have classified organisms according to their intrinsic levels of resistance to antimicrobials, mechanism(s) of resistance development, and concepts such as phenotypic and genotypic resistance to antimicrobial agents. Regarding intrinsic resistance to biocides, in general, it can be stated that gram-negative bacteria are more resistant to biocides than are gram-positive bacteria. In addition to this generalization, there are specific examples of intrinsic resistance of microorganisms, such as mycobacterial, pseudomonad, and fungal species, to biocides.

Microorganisms may also gain the capacity to resist the biocide by the acquisition of gene function(s). These gene functions are mostly concerned with inactivation or modification of the biocide, efflux systems, specification of a new target, or enzymatic modification of the target. Microorganisms could also simply persist in the presence of the biocide. This phenomenon may result from mutation or temporary resistance due to gene regulatory events or phenotypic changes. It is accepted that the general resistance mechanisms producing biocide resistance in microorganisms are the same mechanisms found in antibiotic resistance. Excessive use of biocides may produce organisms with a non-specific mechanism(s) of cross-resistance to other biocides and, most important, to antibiotics (double resistance to biocides and to antibiotics).

Resistance development to industrial biocides has received much attention, and numerous published research articles and reviews have been devoted to this subject. There should be no doubt that the inappropriate and excessive use of biocides often results

in selection of resistant populations. This usually includes unintentional under-dosing and, more important, misunderstanding of the kinetics of biocide effects and the dynamics of the system treated with biocides.

With regard to the resistance categories mentioned previously, there are some points worth noting. When the mechanism of resistance involves inactivation or modification of a biocide and the organism(s) becomes the dominant microbial population in the biocide-treated system, other less susceptible populations may also be protected. There have been reports indicating survival of biocide-sensitive organisms in the presence of resistant populations in metalworking fluids.

The addition of biocides (intermittent slug dosing or continuous addition with pumps) to a system may result in an unintended biocide buildup in which the extremely hostile toxic environment kills virtually all the microbial populations usually found in systems treated with recommended doses of biocide (gram-negative bacteria, especially *Pseudomonas* species). This results in an environment, although hostile, with little or no competition. Microbial populations which could tolerate these conditions will eventually colonize this environment and flourish. There are reports indicating the isolation of unusual organisms in the presence of biocide several times in excess of the recommended dose. The evidence strongly suggests that these organisms have an extremely low permeability to hydrophilic biocides used in the system.

This scenario may be involved in recent outbreaks of hypersensitivity pneumonitis associated with exposure to metalworking fluid aerosols. The evidence suggests that hypersensitivity pneumonitis has occurred where "atypical" flora have predominated in metalworking fluids. Although the microbiological origin of hypersensitivity pneumonitis is strongly suspected, the involvement of biocides and other constituents of the fluids has not been excluded. There have been many reports on allergic contact dermatitis among workers exposed to biocide-treated components of industrial systems and contact sensitization to products containing biocides at the consumer end. These types of reports include most of the frequently used industrial biocides.

X. RECENT DEVELOPMENTS AND CONCERNS OVER RESISTANCE DEVELOPMENT

In July 2001, the OPP of the EPA announced purely voluntary pesticide resistance management labeling guidelines based on mode/target site of action for

agriculturally used herbicides, fungicides, bactericides, and insecticides. This, Pesticide Registration Notice to registrants, concerns pesticide products intended for general agricultural use at this time. One could envision similar notices for all biocides in the future. This possibility becomes even more realistic if new studies establish the existence of cross-resistance between biocides and antibiotics.

This aspect of cross-resistance could be approached considering two scenarios: (a) antibiotic resistant organism is also resistant to biocides; and (b) biocide resistant organism also exhibits cross-resistance to antibiotics. At this time, there is no evidence that antibiotic resistant microorganisms are more resistant to biocides, excluding the intrinsic resistance characteristics of some organisms. There have been reports studying the susceptibility of antibiotic resistant bacteria to disinfectants that suggest the above conclusion.

With the ever increasing use of antimicrobials in consumer products and biocides to control biodeterioration, there is a recent but growing and legitimate concern over cross-resistance of biocide resistant organisms to antibiotics. It is possible that selection of microorganisms with extremely low permeability as a result of biocide treatment may indeed produce populations less accessible to antibiotics. Although similarities between the mechanisms of resistance development to biocides and antibiotics exist, efflux pumps, thickening of the cell wall, outer membrane alterations in gram-negative bacteria, it has not yet been established that biocide use will result in selection of an antibiotic resistance trait in the same organisms.

XI. HANDLING OF BIOCIDES

It should be clear that "biocides" are poisons and are designed to kill living cells. Therefore, direct contact with concentrated biocides (undiluted product) should be avoided. The Material Safety Data Sheet (MSDS) for a biocide should be studied carefully and appropriate personal protective equipment (protective clothing, glasses or face shield, gloves, and other protective material) should be used when handling biocides. If there is any likelihood of exposure through inhalation, then respiratory protection should be included as protective equipment. An emergency action plan should be in place to deal with accidental spill. This should include the decontamination and deactivation of small spills based on recommendations of the biocide manufacturer and in case of major spills, local authorities should be contacted immediately.

Since biocides are considered hazardous materials, disposal of biocides should be done according to regulations and through licensed disposal contractors. Biocide concentrates should not be allowed to enter surface waters, ground waters, wastewater treatment systems or the environment in general.

Biofilms and biofouling

Karen T. Elvers¹ and Hilary M. Lappin-Scott

University of Exeter

GLOSSARY

biofilm Complex association or matrix of microorganisms and microbial products attached to a surface.

biofouling Damage caused to a surface by microorganisms attached to a surface.

consortia Spatial grouping of bacterial cells within a biofilm in which different species are physiologically coordinated with each other, often to produce phenomenally efficient chemical transformations.

planktonic Free-floating bacteria living in the aqueous phase and not associated with a biofilm.

sessile Bacteria living within a biofilm.

Biofilms are generally described as consisting of the cells of microorganisms immobilized at a substratum, attached to a surface, and frequently embedded in an extracellular polymer matrix of microbial origin. In this context, studies have concentrated on bacterial cells rather than on other microorganisms. Bacteria attach firmly to almost any surface submerged in an aquatic environment or bulk liquid. Immobilized bacterial cells within a biofilm are called sessile, whereas those free floating in the aquatic environment are called planktonic. The immobilized cells grow and reproduce, with the newly formed cells attaching to each other as well as to the surface. They also produce extracellular polymers, which extend from the cells to form a matrix of fibers. This matrix entraps debris, nutrients, and other microorganisms establishing a biofilm that has a very

heterogeneous structure and composition. Although bacteria may attach to surfaces in minutes, biofilms can take hours or days to develop. Biofouling refers to the damage caused by biofilms to surfaces. The combination of growth processes, the production of metabolites, and the physical presence of the biofilm can damage the surface and reduce its efficiency or effectiveness.

Early studies on the significance of bacterial adhesion to surfaces emerged from the work of Claude ZoBell in the 1930s. Since this initial research, it is now known that bacterial adhesion is widespread in the environment and the subject of biofilms constitutes an extensive field within microbiology. In addition, modern biofilm studies have shown that biofouling affects a surprisingly wide range of materials. This article contains examples of biofilms in medical and industrial situations and describes how particular biofilms cause damage and resist treatment.

I. BIOFILM FORMATION AND DETACHMENT

Many physical, chemical, and biological processes determine biofilm formation. A general description of biofilm formation on a surface begins with the transportation of molecules and small particles to the surface by molecular diffusion to form a conditioning film. This occurs very rapidly or almost instantaneously on exposure of a surface to an aqueous environment. Its effect is to cause changes in the surface properties,

¹Present address: University of Wales Institute.

including the acquisition of a small negative surface charge and a decrease in hydrophobicity. The composition of the conditioning film varies depending on the surface type but apparently it contains polysaccharides, glycoproteins, and proteins. It is generally uniform in composition and coverage and is an important influence on the subsequent adsorption of bacteria. The growth phase follows the initial phase of biofilm formation.

Fluid dynamics within the aquatic environment play an important role in determining the transport of bacteria to the surface during the growth phase. Under quiescent flow conditions, bacterial transport is affected by gravitational forces, Brownian motion, or motility. Under laminar flow conditions, bacteria are transported to the surface by diffusion with a significant increase in transport rate if the cells are motile. Under turbulent flow conditions, bacteria are transported to the surface by fluid dynamic forces (inertia, lift, drag, drainage, and downsweeps) which can be enhanced by further increasing turbulence and surface roughness. Furthermore, eddies that develop in turbulent flow are able to propel bacteria to the surface. The Reynolds number, which describes the relative magnitude of inertia to viscous forces, can be used to describe whether a system is laminar or turbulent.

Bacteria approaching the surface are subjected to repulsion forces which must be overcome if they are to adsorb to the surface. The outcome of the forces is described by the Derjaguin and Landau; Verwey and Overbeek theory of colloidal stability. The theory postulates two separation distances from the surface where adhesion can occur. Two- and three-step mechanisms have been proposed for the adhesion process, which results in irreversible adsorption usually by the production of exopolysaccharide (EPS). Development of the biofilm includes further attachment, cell growth, cell division, and EPS production resulting in the formation of distinct microcolonies. Mature biofilms then develop by the attraction of more planktonic bacteria and entrapment of inorganic and organic molecules and microbial products, developing a complex consortia within which there is physiological cooperation between different species. This results in increased heterogeneity and the development of chemical microgradients within the biofilm.

With time, portions of the biofilm detach and biofilm development reaches a plateau or steady state of development with accumulation equaling loss by detachment. Detachment is defined as the loss of components (biomass) from the biofilm matrix to the bulk liquid and is a means of interaction and cell turnover between the planktonic organisms in the liquid phase and the sessile organisms within the biofilm. This interaction can affect the overall species

distribution. Detachment occurs by erosion, sloughing, and abrasion. It can be caused by several factors: the action of polymerases from the biofilm organisms, the result of grazing or predator harvesting by protozoa, the effects of substratum texture and surface chemistry, the production of unattached daughter cells through attached cell replication, and the availability of nutrients. Fluid dynamics is also thought to significantly influence detachment, in which an increase in fluid velocity causes an increase in detachment. There are also artificial methods of detachment which aim to control biofilm growth and biofouling, including chemical treatment (chelants, surfactants, and oxidants) and physical treatments (increased fluid velocity, ultrasound, and scrubbing).

II. EPS AND THE GLYCOCALYX

EPS and glycocalyx are terms used to describe the polysaccharide produced by bacterial cells. EPS refers to one of the major components of biofilms, and glycocalyx refers to the polysaccharide matrix surrounding individual cells. EPS has an important role in biofilm structure and function and has a complex physical and chemical nature. Its functions are mostly protective in nature and this is one of the benefits for bacteria in the sessile state. Because the glycocalyx is the outermost component of bacterial cells, this layer mediates virtually all bacterial associations with surfaces and other cells: it dictates location, juxtaposition, and the eventual success in the ecosystem.

EPS production may be a direct response to selective pressures in the environment and may protect against desiccation (by binding water molecules) and predation by feeding protozoa. It also provides protection against antimicrobial agents, including antibiotics, biocides, and host defense mechanisms. This defense may occur by means of a physical barrier or through aiding the bacteria to evade phagocytosis. Other advantages for bacteria of EPS derive from its polyanionic nature, which confers on the biofilm some ion-exchange properties that assist entrapment and the concentration of nutrients, the removal of toxins, and the exchange of metabolites within the consortia. Finally, the close proximity of cells within the biofilm allows plasmid transfer and an alteration in phenotypical characteristics as a response to changes in the environment.

III. BIOFILM STRUCTURE

Biofilm structure has been studied using many techniques, including transmission electron microscopy,

scanning electron microscopy (SEM), and confocal scanning laser microscopy (CSLM). SEM has been used extensively to study the surface architecture of biofilms. The resulting images reveal an uneven outer surface topography, with the high resolution achieved by this method allowing individual cells to be clearly distinguished among a condensed matrix. Although this technique provides valuable information regarding the nature of biofilms, it is not entirely useful because it is well-known that the dehydration stages of sample preparation for SEM can destroy the EPS matrix. CSLM allows nondestructive *in situ* analysis of hydrated biofilms in combination with a wide range of fluorescent compounds. This technique can be used to form 3-D computer reconstructions of biofilms. These show a variable distribution of biomass with bacteria aggregating at different horizontal and vertical sites, with the highest cell densities at the biofilm base or at the top of the biofilm, forming "mushroom," "cone," or "stacks" shapes. Where biofilms have developed under turbulent conditions, they form additional structures termed "streamers." CSLM has also shown that biofilms are highly hydrated and that the total biofilm volume is made up of cell clusters, horizontal and vertical interstitial voids, and conduits beneath the clusters. These clusters and channels produce biofilms of varying depth and structure. Species composition has been shown to be an important determining factor in biofilm structure.

Recently, it was suggested that the structural complexity of biofilms is determined by the organisms through signaling molecules. It has been established that a family of diffusible chemical signals (*N*-acyl homoserine lactones) can regulate the production of virulence determinants and secondary metabolites, in suspended cultures, in a cell density-dependent manner. Also known as quorum sensing, it is thought that this may be important for the formation of biofilms which also contain densely packed cells. Evidence based on a pure culture *Pseudomonas aeruginosa* biofilm growing in laminar flow by Davies and coworkers (1998) supports this theory. They reported that *N*-(3-oxododecanoyl)-L-homoserine lactone (OdDHL) was required for the biofilm to develop a complex structure by comparing wild-type biofilms with a LasI defective mutant (LasI directs the synthesis of OdDHL). This work illustrates the interest in this field, which has a huge potential for biofilm control. However, since quorum sensing is a concentration-dependent phenomenon, it will be strongly influenced by mass transfer processes. It may be expected that quorum sensing will have a greater significance in diffusion-dominated regions such as those found in large cell clusters or channels when bulk liquid flow is very low.

IV. MIXED-SPECIES BIOFILMS

Much of the understanding of biofilm development, activity, and physiology is derived from studying single cultures of bacteria, with relatively few studies having been done on mixed cultures. There has been little discussion of the significance of other species within biofilms (e.g., bacterial and algal interactions and fungi), despite the fact that they are excellent colonizers of surfaces. Fungi are able to respond by growth at a surface and fungal hyphal slimes may have many of the functions attributed to bacterial EPS. These functions include the anchorage of mycelium to the substrate, retardation of desiccation, and service as a source of support and nutrition. Biofilms of filamentous fungi have been involved in industrial processes, such as the degradation of aromatic pollutants, biofouling of cooling tower timbers, voice prostheses, and photoprocessors.

V. TECHNIQUES FOR BIOFILM ANALYSIS

Techniques available to cultivate and study biofilms can be broadly categorized as disruptive and non-disruptive to the biofilm. These include fermentors and sampling devices such as the modified Robbins device (MRD). The MRD contains replaceable surfaces that can be examined (viewed by epifluorescence microscopy and SEM) for viable counts, total carbohydrate, total protein, and metabolic activity. The MRD is versatile in that colonization of different surfaces can be investigated, surface roughness can be controlled, and biocides and antibiotics can be tested.

Chemostats are widely used for studying microorganisms under constant environmental conditions over long periods of time. They can be used to cultivate well-defined two- or three-member mixed cultures or those with even more members. Other reports demonstrate the use of a two-stage chemostat system, with the inoculum grown in the first vessel before being passed to the second. This second or test vessel allows parameters to be changed, e.g., addition of biocide and insertion of coupons of differing materials on which the biofilm develops. Chemostats have also been used in combination with the MRD.

Other biofilm fermentors include the constant depth film fermentor, which allows the biofilm to accumulate to a preset depth which can be maintained, and the continuous perfused biofilm fermentor, which allows establishment of a biofilm on the underside of a cellulose membrane perfused with sterile fresh medium.

Microscopic techniques include light, epifluorescence and electron microscopy, CSLM and computer-enhanced microscopy with image analysis, and Nomarski differential contrast microscopy. Epifluorescence is particularly useful when cells are stained with fluorescent dyes such as acridine orange and propidium iodide, which mark nucleic acids, or those that determine metabolic activity, such as rhodamine and 5-cyano-2,3-ditolylyl tetrazolium chloride. CSLM can be used in combination with microelectrodes which, depending on their construction, can measure oxygen, pH, and sulfide gradients within cell clusters. Voids can be visualized by following the movement of fluorescent latex beads.

Other techniques include the use of continuous-flow cell cultures with image analysis, Fourier transform infrared spectroscopy, nuclear magnetic resonance, atomic force microscopy, and cryosectioning. The data generated from all these techniques have greatly altered the understanding of biofilms in both pure and mixed cultures. They have shown biofilms as being spatially and temporally heterogeneous systems with microscale variations in architecture, chemistry, microgradients, and reactions to antimicrobial agents.

VI. BIOFILMS AND BIOFOULING IN DIFFERENT ENVIRONMENTS: THEIR CONTROL AND RESISTANCE

The phenotypic plasticity of bacteria allows colonization in a wide variety of environments. Adhering bacterial species are inherently different from their planktonic equivalents. In particular, biofilm bacteria are more resistant to medical and industrial control strategies than their planktonic counterparts. Biofilms may be either beneficial or detrimental for their host systems. The following sections discuss the variety and importance of biofilms and biofouling in the context of medical and industrial systems.

A. Biofilms in medical systems

Biofilms affecting human health can be divided into the following categories:

1. Biofilms formed on human tissue. These biofilms occur in the healthy body, for example, on teeth, in the digestive tract, and in the female genital tract. They may have a role in prevention of certain infections but can be overgrown by pathogenic microorganisms.

2. Biofilms formed on medical implants within the body.

3. Biofilms formed on surfaces outside the body that may harbor harmful pathogens. Examples of

these surfaces include those in water systems that may harbor potentially pathogenic bacteria such as *Legionella* sp. and that consequently may be protected from chlorination. Biofilms have also been found on contact lenses and contact lens storage cases, for which bacteria induce severe eye irritation and inflammation and may play a role in persistence of the organisms.

In all cases, once established, the biofilm's resistance to phagocytosis and antibiotics allows the organism within it to continue living after planktonic organisms in the same environment have been killed by treatment.

Artificial implants are used for the replacement of diseased or damaged body parts, e.g., joint or vascular prostheses. Many temporary devices, (e.g., urinary catheters, intravascular catheters, and endotracheal tubes) are inserted into patients for various lengths of time. Many inert materials are used for such devices, including vitallium, titanium, stainless steel, polyethylene, polymethyl methacrylate, silicone rubber polytetrafluoroethylene (Teflon), and polyvinyl chloride. All of these can serve as substrata for bacterial biofilms.

A variety of bacteria are involved in the colonization of implants. These include gram-negative organisms (e.g., *Pseudomonas aeruginosa* and *Escherichia coli*) and gram-positive bacteria (e.g., *Staphylococcus aureus* and *S. epidermidis*). The latter, which are normally found on the skin, possess a high degree of adhesiveness to the prosthetic device surface. In the biofilm these species are protected from the effects of antibiotics and they can act as the disseminating center for infection. In addition, biofilm formation can also lead to malfunction of the device and destruction of adjacent tissue. Biofilms have been the cause of significant problems for patients receiving artificial hearts (Jarvik hearts).

In cystic fibrosis, patients' lungs become chronically infected by EPS-producing strains of *P. aeruginosa*. This bacterium has also been found frequently in catheterized patients. The production of large amounts of EPS and copious quantities of mucous by *P. aeruginosa* allows it to cause persistent infections. Isolation of mucoid strains and subsequent subculture results in reversion to non-mucoid colonies. This suggests that the host defense mechanisms must have a selective effect in favor of the mucoid strains. Treatment with antibiotics further selects for the mucoid strains. The mucous and EPS protects *P. aeruginosa* from attack by antibiotics, surfactants, and macrophages. It has been shown that EPS is a large anionic hydrated matrix that can partition charged molecules, preventing them from reaching the bacterial cell.

Silicone is a material that is widely used for tubing, catheters, mammary and testicular implants, and

voice prostheses. Voice prostheses become colonized rapidly by mixed biofilms of bacteria and yeasts and these devices must be removed and replaced frequently before infection can be eradicated. It has been shown by SEM that voice prostheses become damaged by the yeast cells, which grow under the silicone surface. Treatment of infections for short-term devices, such as urinary and intravenous catheters, consists of their immediate removal followed by administration of antibiotics to the patient.

Urinary tract infections are most commonly caused by *E. coli*, *Proteus mirabilis*, *Enterococcus*, and *Streptococcus* spp., found in the gastrointestinal tract, and by pathogens directly transmitted through sexual activity. These infections include acute and chronic cystitis, struvite urolithiasis, chronic prostatitis, and catheter-associated infections. Once the microorganisms are established, they adopt the biofilm mode of growth. The bladder resists infection by the periodic passing of urine, which washes out unattached pathogens, and by sloughing of colonized uroepithelial cells on the glycosaminoglycan (GAG) mucous layer. The GAG layer is a very thin cover on the cell epithelium of the bladder that physically shields the bladder from surface pathogens. Catheter-associated infections increase by approximately 10% each day the catheter is in place. The organisms initially colonize the external surfaces, form a biofilm, and ascend into the bladder where the biofilm can act as a source of infection for the bladder and kidneys. Mineralization can also occur, which can reduce the diameter or block the catheter. Frequent replacement of catheters would reduce infections but is not always practical. Methods to control biofilm growth on catheters are being investigated and include the development of materials that block or kill adherent organisms. These methods include altering the hydrophobicity of polymers and the incorporation of disinfectants and antibiotics in the design of the implant.

Surfaces within the mouth become readily colonized with bacterial deposits, forming a biofilm, usually called dental plaque. By attaching to the teeth or dental implants, the biofilm helps to prevent colonization of the mouth by pathogenic bacteria. Although dental plaque forms naturally without good oral hygiene, it can be a source of dental caries or periodontal disease. The attached organisms obtain nutrients from the ingested food, saliva, and gingival crevice fluid found between the teeth and gums: It is thought that most of the nutrients are derived from the host rather than the from the host's diet.

Environmental factors that contribute to plaque formation are an optimum temperature of 35 or 36 °C and a neutral pH. The pH can become more acidic

when carbohydrates are metabolized or more alkaline during an inflammatory host response. These local changes in pH can lead to shifts in the colonized species. The resident microflora of dental plaque is extremely diverse and consists of gram-positive and -negative bacteria. Few are truly aerobic; most are facultatively or obligately anaerobic. These include *Streptococcus*, *Neisseria*, *Actinomyces*, *Lactobacillus*, *Corynebacterium*, and *Fusobacterium* species, but there are many others and not all are culturable in the laboratory. Sometimes, a particular species will colonize a preferred habitat in the oral cavity, e.g., *Streptococcus mutans* colonizes the occlusal fissures.

Formation of dental plaque begins by the adsorption of a proteinaceous conditioning film or acquired pellicle which is composed of albumin, lysozyme, glycoproteins, and lipids from saliva and gingival cervical fluid. The first colonizers are streptococci and actinomycetes, which rapidly divide to form microcolonies that quickly change into a confluent film of varying thickness. Species diversity increases with the attachment of rods and filaments and layering that is attributable to bacterial succession. Unusual combinations of bacteria such as "corn-cobs" (gram-positive filaments covered by cocci), "rosettes" (cocci covered by small rods), or "bristle brushes" (large filaments surrounded by rods) are seen under SEM.

If plaque formation continues undisturbed for weeks, its composition will vary with location on the teeth. Different environmental conditions exist on and between the teeth, resulting in different chemical gradients and shear forces. The bacterial communities are thought to form as a result of short-range specific molecular interactions between the bacterial cell adhesions of primary colonizers and host receptors in the conditioning film, the attachment of secondary colonizers to primary colonizers (coaggregation) and EPS synthesis and growth. Coaggregation has a major role in forming the distinct patterns in plaque.

Dental caries are formed as a result of the localized dissolution of the tooth enamel by acids produced by metabolism of carbohydrates, lowering the pH and favoring the growth of mutans streptococci and lactobacilli. Periodontal diseases occur when the supporting tissues of the teeth are attacked by obligately anaerobic gram-negative rods, filaments, or spiral-shaped bacteria. Prevention of dental plaque is by efficient oral hygiene (brushing and flossing can almost completely prevent plaque-mediated diseases), fluoridization of drinking water, and the addition of antiplaque or antimicrobial agents to toothpastes and mouthwashes.

Biofilms are central to the survival of bacteria when they are attacked by the normal host immune system or antibiotics. Gram-positive and -negative bacteria

activate the complement system, with the major components causing this reaction being peptidoglycan and lipopolysaccharide, respectively. Activation of complement would eradicate the serum-sensitive bacteria but may also react to live or dead bacteria or bacterial fragments. Continual production of complement may destroy the tissues. Studies on the immune response to biofilms have concentrated on *P. aeruginosa* and infection in cystic fibrosis patients. It was shown that biofilm-grown *P. aeruginosa* was able to resist complement action. The biofilm bacteria activated the complement system to a lesser extent than did the planktonic bacteria. However, some fragments of the activated complement were deposited on the biofilm contributing to chronic inflammation.

B. Biofilms in industrial systems

Biofilm formation in industries involves the ability of the biofilm to act as a reservoir for potential pathogens and in instances in which the biofilm causes surface damage. The degree of contamination in a system is often measured by planktonic counts that fail to detect the presence of sessile bacteria and this leads to incorrect conclusions regarding the level of pathogens in the system. In the water industry, biofilms form on the pipe surfaces that connect the consumer to the supply. The level of biofilm formation is difficult to monitor in these situations, and levels of coliforms, pseudomonads, and *Flavobacterium* sp., detaching from biofilms, have been reported as being higher than permitted the levels. Treatment with chlorine does not control the problem because the biofilm bacteria are protected from the disinfectant. There is also evidence of accelerated material deterioration (corrosion) due to biofilm accumulation in water distribution pipes.

Excessive biofilm accumulation in porous media, on heat exchanger surfaces, and in storage tanks is responsible for reduced efficiency of heat transfer and reduction of flow rates. Transfer of heat is reduced because the thick surface growth physically prevents an efficient heat exchange between the liquid phase and the cooling surface.

Biofilms on ship hulls consist of diatoms, single-celled algae, and bacteria. This biofilm growth reduces speed in the water and increases fuel consumption. As the biofilm develops, the hull must be physically cleaned, which results in further expense. In an attempt to control this growth, antifouling paints have been used. These are not always effective; although good at preventing colonization of small animals, they do not stop bacterial growth.

Corrosion in marine environments on structures such as oil rigs is a result of biofilms that contain

sulfate-reducing or acid-producing bacteria. These microorganisms create anodes and cathodes on metal surfaces. This unequal distribution of ions causes electrical currents, resulting in metal loss. Ideal anaerobic conditions for the biofouling action of sulfate-reducing bacteria are found around oil rig legs.

Biofilms in the food processing industry may form on food contact and non-contact surfaces. These biofilms may contain food spoilage and pathogenic micro-organisms which affect the quality and safety of the food product by reducing shelf life and increasing the probability of food poisoning. Stainless steel is commonly used as a food contact surface because it is chemically and physiologically stable at a variety of processing temperatures, easy to clean, and has a high resistance to corrosion. Food processing environments provide a variety of conditions that favor the formation of biofilms, e.g., flowing water, suitable attachment surfaces, ample nutrients (although possibly sporadic), and the raw materials or the natural flora providing the inocula; however, these conditions may be extremely varied. Time available for biofilm development is relatively short; for example, the production line may run for a few hours before cleaning. Various preventative and control strategies, such as hygienic plant lay-out and design of equipment, choice of materials, correct use and selection of detergents and disinfectants, coupled with physical methods, can be applied for controlling biofilm formation on food contact surfaces.

Biofilms have been shown to occur in many food environments. In the dairy industry, pasteurization ensures the destruction of pathogens and most vegetative organisms within raw milk. However, heat-resistant organisms and spores survive and may form biofilms that could result in post-pasteurization contamination. Biofilms have been found on gaskets and "O" rings from the pipes within the dairy industry. Pathogens, *Listeria* and *Bacillus* sp., have also been isolated from food contact and environmental surfaces in the dairy industry. Biofilms have been found in pipes of breweries, on rubber seals, conveyor belts, and in waste-water pipes, and in flour mills and malt houses. There is also evidence of microbial adherence to environmental surfaces during poultry processing. This could result in cross-contamination during the slaughter process, which may play an important role in product contamination with *Listeria*, *Campylobacter*, and *Staphylococcus aureus*.

Biological warfare

James A. Poupard and Linda A. Miller

SmithKline Beecham Pharmaceuticals

GLOSSARY

biological warfare Use of microorganisms, such as bacteria, fungi, viruses, and rickettsiae, to produce death or disease in humans, animals, or plants. The use of toxins to produce death or disease is often included under the heading of BWR (U.S. Army definition, included in U.S. Army report to the Senate Committee on Human Resources, 1977).

biological weapons Living organisms, whatever their nature, which are intended to cause disease or death in man, animals, or plants and which depend for their effects on their ability to multiply in the person, animal, or plant attacked [United Nations definition, included in the report of the secretary general titled "Chemical and Bacteriological (Biological) Weapons and the Effects of Their Possible Use," 1969].

genetic engineering Methods by which the genomes of plants, animals, and microorganisms are manipulated: includes but is not limited to recombinant DNA technology.

recombinant DNA technology Techniques in which different pieces of DNA are spliced together and inserted into vectors such as bacteria or yeast.

toxin weapon(s) Any poisonous substance, whatever its origin or method of production, which can be produced by a living organism, or any poisonous isomer, homolog, or derivative of such a substance (U.S. Arms Control and Disarmament Agency definition, proposed on August 20, 1980).

The Most General Concept of Biological Warfare involves the use of any biological agent as a weapon directed against humans, animals, or crops with the intent to kill, injure, or create a sense of havoc against a target population. This agent could be in the form of a viable organism or a metabolic product of that organism, such as a toxin. This article will focus on the use of viable biological agents because many of the concepts relating to the use of toxins are associated more with chemical warfare. The use of viable organisms or viruses involves complex issues that relate to containment. Once such agents are released, even in relatively small numbers, the focus of release has the potential to enlarge to a wider population due to the ability of the viable agent to proliferate while spreading from one susceptible host to another.

I. INTRODUCTION

As the twentieth century draws to a close three events mark significant alterations in the concept of biological warfare (BW): the end of the Cold War, the open threat of using BW agents in the Gulf War, and the realization that the developed world is quite susceptible to attack by radical terrorists employing BW agents. These events mark major changes in the concept of BW and transform the subject from one which was once limited to the realm of political and military policy makers to one that must be considered by a wide range of urban disaster planners, public health officials, and the general public. BW is a complex

subject that is difficult to understand without a basic knowledge of a long and convoluted history. BW can be traced to ancient times and has evolved into more sophisticated forms with the maturation of the science of bacteriology and microbiology. It is important to understand the history of the subject because often there are preconceived notions of BW that are not based on facts or involve concepts related more to chemical rather than biological warfare. Many of the contemporary issues relating to BW deal with Third World conflicts, terrorist groups, or nonconventional warfare. An understanding of these issues is important because many of the long-standing international treaties and conventions on BW were formulated either in an atmosphere of international conflict or during the Cold War period of international relations. Many of the classic issues have undergone significant alteration by recent events. The issue of BW is intimately bound to such concepts as offensive versus defensive research or the need for secrecy and national security. It is obvious that BW will continue to demand the attention of contemporary students of microbiology and a wide range of specialists during the twenty-first century.

II. HISTORICAL REVIEW

A. 300 BC to 1925

Many early civilizations employed a crude method of warfare that could be considered BW as early as 300 BC when the Greeks polluted the wells and drinking water supplies of their enemies with the corpses of animals. Later, the Romans and Persians used these same tactics. All armies and centers of civilization need palatable water to function, and it is clear that well pollution was an effective and calculated method for gaining advantage in warfare. In 1155 at a battle in Tortona, Italy, Barbarossa broadened the scope of BW by using the bodies of dead soldiers as well as animals to pollute wells. Evidence indicates that well poisoning was a common tactic throughout the classical, medieval, and Renaissance periods. In modern times, this method has been employed as late as 1863 during the Civil War by General Johnson, who used the bodies of sheep and pigs to pollute drinking water at Vicksburg.

Catapults and siege machines in medieval warfare were a new technology for delivering biological entities. In 1422 at the siege of Carolstein, catapults were used to project diseased bodies over walled fortifications, creating fear and confusion among the people under siege. The use of catapults as weapons was well established by the medieval period, and projecting diseased bodies over walls was an effective strategy employed by

besieging armies. The siege of a well-fortified position could last for months or years, and it was necessary for those outside the walls to use whatever means available to cause disease and chaos within the fortification. This technique became commonplace, and numerous classical tapestries and works of art depict diseased bodies or the heads of captured soldiers being catapulted over fortified structures.

In 1763, BW took a significant turn from the crude use of diseased corpses to the introduction of a specific disease, smallpox, as a weapon in the North American Indian wars. It was common knowledge at the time that the Native American population was particularly susceptible to smallpox, and the disease may have been used as a weapon in earlier conflicts between European settlers and Native Americans. In the spring of 1763, Sir Jeffrey Amherst, the British commander-in-chief in North America, believed the western frontier, which ran from Pennsylvania to Detroit, was secure, but the situation deteriorated rapidly during the next several months. The Indians in western Pennsylvania were becoming particularly aggressive in the area near Fort Pitt (Pittsburgh). It became apparent that unless the situation was resolved, western Pennsylvania would be deserted and Fort Pitt isolated. On June 23, 1763, Colonel Henry Bouquet, the ranking officer for the Pennsylvania frontier, wrote to Amherst, describing the difficulties Captain Ecuyer was having holding the besieged Fort Pitt. These difficulties included an outbreak of smallpox among Ecuyer's troops. In his reply to Bouquet, Amherst suggested that smallpox be sent among the Indians to reduce their numbers. This well-documented suggestion is significant because it clearly implies the intentional use of smallpox as a weapon. Bouquet responded to Amherst's suggestion by stating that he would use blankets to spread the disease.

Evidence indicates that Amherst and Bouquet were not alone in their plan to use BW against the Indians. While they were developing a plan of action, Captain Ecuyer reported in his journal that he had given two blankets and handkerchiefs from the garrison smallpox hospital to hostile chiefs with the hope that the disease would spread. It appears that Ecuyer was acting on his own and did not need persuasion to use whatever means necessary to preserve the Pennsylvania frontier. Evidence also shows that the French used smallpox as a weapon in their conflicts with the native population.

Smallpox also played a role in the American Revolutionary War, but the tactics were defensive rather than offensive: British troops were vaccinated against smallpox, but the rebelling American colonists were not. This protection from disease gave the British an advantage for several years, until Washington ordered vaccination of all American troops.

It is clear that by the eighteenth century BW had become disease oriented, even though the causative agents and mechanisms for preventing the spread of diseases were largely unknown. The development of the science of bacteriology in the nineteenth and early twentieth centuries considerably expanded the scope of potential BW agents. In 1915, Germany was accused of using cholera in Italy and plague in St. Petersburg. Evidence shows that Germany used glanders and anthrax to infect horses and cattle, respectively, in Bucharest in 1916 and employed similar tactics to infect 4500 mules in Mesopotamia the next year. Germany issued official denials of these accusations. Although there apparently was no large-scale battlefield use of BW in World War I, numerous allegations of German use of BW were made in the years following the war. Britain accused Germany of dropping plague bombs, and the French claimed the Germans had dropped disease-laden toys and candy in Romania. Germany denied the accusations.

Although chemical warfare was far more important than BW in World War I, the general awareness of the potential of biological weapons led the delegates to the Geneva Convention to include BW agents in the 1925 Protocol for the Prohibition of the Use in War of Asphyxiating, Poisonous or Other Gases, and of Bacteriological Methods of Warfare. The significance of the treaty will be discussed in Section III.

B. 1925–1990

The tense political atmosphere of the period following the 1925 Geneva Protocol and the lack of provisions to deter biological weapons research had the effect of undermining the treaty. The Soviet Union opened a BW research facility north of the Caspian Sea in 1929; the United Kingdom and Japan initiated BW research programs in 1934. The Japanese program was particularly ambitious and included experiments on human subjects prior to and during World War II.

Two factors were significant in mobilizing governments to initiate BW research programs: (i) continuing accusations regarding BW and (ii) the commitment of resources for BW research by several national adversaries, thus creating insecurity among governments. The presence of BW research laboratories in nations that were traditional or potential adversaries reinforced this insecurity. Thus, despite the Geneva Protocol, it was politically unwise for governments to ignore the threat of BW, and the result was increasingly sophisticated biological weapons.

In 1941, the United States and Canada joined other nations and formed national programs of BW research and development. Camp Detrick (now Fort

Detrick) became operational as the center for U.S. BW research in 1943, and in 1947 President Truman withdrew the Geneva Protocol from Senate consideration, citing current issues such as the lack of verification mechanisms that invalidated the underlying principles of the treaty. However, there was no widespread use of BW in a battlefield setting during World War II. BW research, however, continued at an intense pace during and after the war. By the end of the decade, the United States, the United Kingdom, and Canada were conducting collaborative experiments involving the release of microorganisms from ships in the Caribbean. In 1950, the U.S. Navy conducted open-air experiments in Norfolk, Virginia, and the U.S. Army conducted a series of airborne microbial dispersals over San Francisco using *Bacillus globigii*, *Serratia marcescens*, and inert particles.

Not surprisingly, the intense pace of BW research led to new accusations of BW use, most notably by China and North Korea against the United States during the Korean War. In 1956, the United States changed its policy of “defensive use only” to include possible deployment of biological weapons in situations other than retaliation. During the 1960s, all branches of the U.S. military had active BW programs, and additional open-air dissemination experiments with stimulants were conducted in the New York City subway system. By 1969, however, the U.S. military concluded that BW had little tactical value in battlefield situations, and since it was believed that nuclear weapons dominated the strategic equation the United States would be unlikely to need or use BW. Thus, President Nixon announced that the United States would unilaterally renounce BW and eliminate stockpiles of biological weapons. This decision marked a turning point in the history of BW: Once the U.S. government made it clear it did not consider biological weapons a critical weapon system, the door was opened for negotiation of a strong international treaty against BW.

Once military strategists had discounted the value of BW, an attitude of openness and compromise on BW issues took hold, leading to the 1972 Convention on the Prohibition of the Development, Production and Stockpiling of Bacteriological (Biological) and Toxin Weapons and on Their Destruction (see Section III). The parties to the 1972 convention agreed to destroy or convert to peaceful use all organisms, toxins, equipment, and delivery systems. Following the signing of the 1972 treaty, the U.S. government generated much publicity about its compliance activities, inviting journalists to witness destruction of biological weapons stockpiles.

The problem of treaty verification beleaguered the 1972 convention. Press reports accusing the Soviet

Union of violating the treaty appeared as early as 1975. When an outbreak of anthrax was reported in Sverdlovsk, Soviet Union, in 1979, the United States claimed it was caused by an incident at a nearby Soviet biological defense laboratory that had released anthrax spores into the surrounding community. The Soviet government denied this allegation, claiming the outbreak was caused by contaminated black market meat.

BW continued to be discussed in the public media throughout the 1980s. In 1981, reports describing the American "cover-up" of Japanese BW experiments on prisoners of war began to surface in the public and scientific literature. In 1982, *The Wall Street Journal* published a series of articles on Soviet genetic engineering programs that raised many questions about the scope of Soviet BW activities. The environmental effects of testing biological agents at Dugway Proving Grounds in Utah received considerable press attention in 1988, leading to a debate over the need for such a facility.

The 1980s also were characterized by debate over larger issues relating to BW. A public debate in 1986 considered the possible role of biological weapons in terrorism. Scientific and professional societies, which had avoided discussing BW for many years, began considering both specific issues, such as Department of Defense support for biological research, and more general issues, such as adopting ethical codes or guidelines for their members.

C. 1990 and contemporary developments

The last decade of the twentieth century witnessed three significant events that will have long-term effects on developing policies relating to BW. The first event was the demise of the Soviet Union. Most U.S. defensive research was directed to counter potential use by the Soviet Union. As the wall of Soviet secrecy eroded during the 1990s the extent of the Soviet BW program became apparent. There is international concern that many unemployed BW researchers will find work as advisors for developing countries that view BW as a rational defense strategy, especially those countries without nuclear capability or those without restrictive laws against radical terrorist groups. This is an ongoing issue without readily apparent solutions.

The second major event was the Gulf War. The open threat by the Iraqi military to use BW agents raised serious concerns and changed attitudes about BW. The plans for Operation Desert Storm included provisions for protective equipment and prophylactic administration of antibiotics or vaccines to protect against potential biological weapons. Many of the critics of the U.S. Biological Defense Research Program (BDRP) were now asking why the country was not

better prepared to protect its troops against biological attack. Fortunately, BW was not used during the Gulf War, but the threat of its use provided several significant lessons. Although there was considerable concern that genetic engineering would produce new, specialized biological weapons, most experts predicted that "classical" BW agents, such as anthrax and botulism, would pose the most serious threats to combat troops in Operation Desert Storm. Efforts by the United Nations after the war to initiate inspection programs demonstrated the difficulty of verifying the presence of production facilities for BW agents; these difficulties highlight the need for verification protocols for the BW convention. Verification and treaty compliance are major contemporary BW issues. Following the Gulf War the extent of the intense Iraq BW research programs demonstrated the inadequacy of all estimates and post war verification procedures of Iraq BW capacity.

The third significant contemporary development is the realization that urban centers and public facilities are vulnerable to attack by terrorists employing BW agents. Local and national governments are now realizing the extent of this vulnerability and are taking early measures to formulate policies to address these issues. Much work remains to be accomplished in this area.

III. INTERNATIONAL TREATIES

A. The 1925 Geneva protocol

The 1925 Geneva Protocol was the first international treaty to place restrictions on BW. The Geneva Protocol followed a series of international agreements that were designed to prohibit the use in war of weapons that inflict or prolong unnecessary suffering of combatants or civilians. The St. Petersburg Declaration of 1868 and the International Declarations Concerning the Laws and Customs of War, which was signed in Brussels in 1874, condemned the use of weapons that caused useless suffering. Two major international conferences were held at the Hague in 1899 and 1907. These conferences resulted in declarations regarding the humanitarian conduct of war. The conference regulations forbid nations from using poison, treacherously wounding enemies, or using munitions that would cause unnecessary suffering. The so-called Hague Conventions also prohibited the use of projectiles to diffuse asphyxiating or deleterious gases. The Hague Conventions still provide much of the definitive law of war as it exists today.

The Hague Conventions did not specifically mention BW, due in part to the lack of scientific understanding of

the cause of infectious diseases at that time. The conventions have, however, been cited as an initial source of the customary international laws that prohibit unnecessary suffering of combatants and civilians in war. Although biological weapons have been defended as humanitarian weapons on the grounds that many biological weapons are incapacitating but not lethal, there are also biological weapons that cause a slow and painful death. It can be argued, therefore, that the Hague Conventions helped to set the tone of international agreements on laws of war that led to the 1925 Geneva Protocol.

The 1925 Geneva Protocol, formally called the Prohibition of the Use in War of Asphyxiating, Poisonous or Other Gases, and of Bacteriological Methods of Warfare, was opened for signature on June 17, 1925 in Geneva. More than 100 nations signed and ratified the protocol, including all members of the Warsaw Pact and North Atlantic Treaty Organization (NATO). The 1925 Geneva Protocol was initially designed to prevent the use in war of chemical weapons; however, the protocol was extended to include a prohibition on the use of bacteriological methods of warfare. The Geneva Protocol distinguishes between parties and nonparties by explicitly stating that the terms of the treaty apply only to confrontations in which all combatants are parties and when a given situation constitutes a "war." In addition, many nations ratified the Geneva Protocol with the reservation that they would use biological weapons in retaliation against a biological weapons attack. This resulted in the recognition of the Geneva Protocol as a "no first-use" treaty.

B. The 1972 biological warfare convention

International agreements governing BW have been strengthened by the 1972 BW convention, which is officially called the 1972 Convention on the Prohibition of the Development, Production and Stockpiling of Bacteriological (Biological) and Toxin Weapons and on Their Destruction. The convention was signed simultaneously in 1972 in Washington, London, and Moscow and entered into force in 1975. The preamble to the 1972 BW convention states the determination of the parties to the treaty to progress toward general and complete disarmament, including the prohibition and elimination of all types of weapons of mass destruction. This statement places the convention in the wider setting of international goals of complete disarmament. The 1972 BW convention is also seen as a first step toward chemical weapons disarmament.

The 1972 BW convention explicitly builds on the Geneva Protocol by reaffirming the prohibition of the use of BW in war. The preamble, although not legally binding, asserts that the goal of the convention is to

completely exclude the possibility of biological agents and toxins being used as weapons and states that such use would be repugnant to the conscience of humankind. The authors of the 1972 convention, therefore, invoked societal attitudes as justification for the existence of the treaty.

The 1972 BW convention evolved, in part, from a process of constant reevaluation of the Geneva Protocol. From 1954 to the present, the United Nations has periodically considered the prohibition of chemical and biological weapons. The Eighteen-Nation Conference of the Committee on Disarmament, which in 1978 became the Forty-Nation Committee on Disarmament, began talks in 1968 to ban chemical weapons. At that time, chemical, toxin, and biological weapons were being considered together in an attempt to develop a comprehensive disarmament agreement. However, difficulties in reaching agreements on chemical warfare led to a series of separate negotiations that covered only BW and toxin weapons. The negotiations resulted in the drafting of the 1972 BW convention.

The 1972 BW convention consists of a preamble followed by 15 articles. Article I forms the basic treaty obligation. Parties agree never in any circumstance to develop, produce, stockpile, or otherwise acquire or retain the following:

1. Microbial or other biological agents, or toxins whatever their origin or method of production, of types and in quantities that have no justification for prophylactic, protective, or other peaceful purposes.
2. Weapons, equipment, or means of delivery designed to use such agents or toxins for hostile purposes or in armed conflict.

Article II requires each party to destroy, or divert to peaceful purposes, all agents, toxins, equipment, and delivery systems that are prohibited in Article I and are under the jurisdiction or control of the party. It also forbids nations from transferring, directly or indirectly, materials specified in Article I and prohibits nations from encouraging, assisting, or inducing any state, group of states, or international organizations from manufacturing or acquiring the material listed in Article I. There is no specific mention of subnational groups, such as terrorist organizations, in the treaty.

Articles IV requires each party to the convention to take any measures to ensure compliance with the terms of the treaty. Article IV has been interpreted by some states as the formulation of civil legislation or regulations to ensure adherence to the convention. This civil legislation could regulate activities by individuals, government agencies, universities, or corporate groups.

Articles V–VII specify procedures for pursuing allegations of noncompliance with the 1972 BW convention. The United Nations plays an integral part in all the procedures for investigating allegations of noncompliance. According to Article VI, parties may lodge a complaint with the Security Council of the United Nations if a breach of the treaty is suspected. All parties must cooperate with investigations that may be initiated by the Security Council. Article VII requires all parties to provide assistance or support to any party that the Security Council determines has been exposed to danger as a result of violation of the convention. Articles VII–IX are general statements for obligations of the parties signing the protocol. Article X gives the parties the right to participate in the fullest possible exchange of equipment, materials, and scientific or technological information of the use of bacteriological (biological) agents and toxins for peaceful purposes. Article XI allows parties to propose amendments to the convention. The amendments only apply to those states that accept them and enter into force after a majority of the states' parties to the convention have agreed to accept and be governed by the amendment.

Article XII requires that a conference be held 5 years after the entry into force of the BW convention. Article XIV states that the 1972 BW convention is of unlimited duration. A state party to the treaty is given the right to withdraw from the treaty if it decides that extraordinary events, related to the subject matter of the convention, have jeopardized the supreme interests of the country. This article also opens the convention to all nations for signature. Nations that did not sign the convention before its entry into force may accede to it at any time.

C. Review conferences

The 1972 convention contained a stipulation that a conference be held in Geneva 5 years after the terms of the convention entered into force. The purpose of the conference was to review the operation of the convention and to ensure that the purposes of the convention were being realized. The review was to take into account any new scientific and technological developments that were relevant to the convention. The first review conference was held in Geneva in 1980. Several points contained in the original convention were clarified at this conference. The second review conference was held in 1986, and a third was held in 1991. There is general agreement that these conferences and the one that followed serve a definite function in solving contemporary problems that need clarification based on changing events and have made significant contributions in keeping the 1972 convention relevant to the needs of a changing world situation.

TABLE 13.1 Representative organisms regulated by the CDC

Bacteria	Viruses
<i>Bacillus anthracis</i>	Crimean–Congo hemorrhagic fever virus
<i>Brucella abortus, melitensis, suis</i>	Eastern equine encephalitis virus
<i>Burkholderia mallei, pseudomallei</i>	Ebola virus
<i>Clostridium botulinum</i>	Equine morbillivirus
<i>Francisella tularensis</i>	Lassa fever virus
<i>Yersinia pestis</i>	Marburg virus
	Rift Valley fever virus
	South American hemorrhagic fever viruses
Rickettsiae	Tick-borne encephalitis complex virus
<i>Coxiella burnetii</i>	Variola (smallpox) major virus
<i>Rickettsia prowazekii</i>	Venezuelan equine encephalitis virus
<i>Rickettsia rickettsii</i>	Hantavirus
	Yellow fever virus

D. Additional U.S. laws and acts

The following U.S. laws have been enacted since 1989 that impact on BW:

- Biological Weapons and Anti-Terrorist Act (1989): established as a federal crime the development, manufacture, transfer, or possession of any biological agent, toxin, or delivery system for use as a weapon.
- Chemical and Biological Weapons Control Act (1991): places sanctions on companies that knowingly export goods or technologies relating to biological weapons to designated prohibited nations.
- The Defense Against Weapons of Mass Destruction Act (1996): designed to enhance federal, state and local emergency response capabilities to deal with terrorist incidents.
- Antiterrorism and Effective Death Penalty Act (1996): established as a criminal act any threat or attempt to develop BW or DNA technology to create new pathogens or make more virulent forms of existing organisms.
- Centers for Disease Control (CDC) Hazardous Biological Agent Regulation (1997): identification of infective agents that pose a significant risk to public health. Some of the organisms regulated by the CDC are listed in Table 13.1.

IV. CURRENT RESEARCH PROGRAMS

Biological weapons research in the United States is under the direction of the BDRP, headquartered at Fort Detrick, Maryland. In accordance with official U.S. policy, the BDRP is solely defensive in nature,

with the goal of providing methods of detection for, and protective measures against, biological agents that could be used as weapons against U.S. forces by hostile states or individuals.

Current U.S. policy stems from the 1969 declaration made by President Nixon that confined the U.S. BW program to research on biological defense such as immunization and measures of controlling and preventing the spread of disease. Henry Kissinger further clarified the U.S. BW policy in 1970 by stating that the United States biological program will be confined to research and development for defensive purposes only. This did not preclude research into those offensive aspects of biological agents necessary to determine what defensive measures are required.

The BDRP expanded significantly in the 1980s in an apparent response to alleged treaty violations and perceived offensive BW capabilities of the Soviet Union. These perceptions were espoused primarily by representatives of the Reagan administration and the Department of State. At congressional hearings in May 1988, the U.S. government reported that at least 10 nations, including the Soviet Union, Libya, Iran, Cuba, Southern Yemen, Syria, and North Korea, were developing biological weapons. Critics of the U.S. program refuted the need for program expansion.

The BDRP is administered through two separate government organizations—the army and the CIA. Details of the program are described in the April 1989 Environmental Impact Statement published by the Department of the Army, U.S. Army Medical Research and Development Command.

The BDRP is located at three sites: the U.S. Army Medical Research Institute of Infectious Diseases (USAMRIID) at Fort Detrick, Maryland; the Aberdeen Proving Ground in Maryland; and the Dugway Proving Ground in Utah. USAMRIID is designated as the lead laboratory in medical defense against BW threats. Research conducted at the USAMRIID focuses on medical defense such as the development of vaccines and treatments for both natural diseases and potential BW agents. Work on the rapid detection of microorganisms and the diagnosis of infectious diseases is also conducted. The primary mission at the Aberdeen Proving Ground is nonmedical defense against BW threats including detection research, such as the development of sensors and chemiluminescent instruments to detect and identify bacteria and viruses, and development of methods for material and equipment decontamination. The U.S. Army Dugway Proving Ground is a Department of Defense major range and test facility responsible for development, testing, evaluation, and operation of chemical warfare equipment, obscurants and smoke munitions,

and biological defense equipment. Its principle mission with respect to the BDRP is to perform developmental and operational testing for biological defense material, including the development and testing of sensors, equipment, and clothing needed for defense against a BW attack.

One hundred secondary sites have received contracts for biological defense research. Secondary sites include the Swiftwater Lab, operated by the Salk Institute in Swiftwater, Pennsylvania; the Naval Medical Research Institute in California; medical centers; universities; and private biotechnology firms in the United States, Scotland, and Israel.

The CIA also participates in the administration of the BDRP. In 1982, Thomas Dashiell of the office of the secretary of defense reported on a classified technology watch program related to BW that was operated by the intelligence community. The program was designed to monitor worldwide developments related to BW that could affect the vulnerability of U.S. and NATO forces to biological attack.

BDRP research focuses on five main areas:

1. Development of vaccines.
2. Development of protective clothing and decontamination methods.
3. Analysis of the mode of action of toxins and the development of antidotes.
4. Development of broad-spectrum antiviral drugs for detecting and diagnosing BW agents and toxins.
5. Utilization of genetic engineering methods to study and prepare defenses against BW and toxins.

The BDRP has often been a center of controversy in the United States. One BDRP facility, the Dugway Proving Ground, was the target of a lawsuit that resulted in the preparation of the environmental impact statement for the facility. A proposal for a high-level containment laboratory (designated P-4) was ultimately changed to a plan for a lower-level (P-3) facility.

The use of genetic engineering techniques in BDRP facilities has also been a focus of controversy. The BDRP takes the position that genetic engineering will be utilized if deemed necessary. The Department of Defense stated that testing of aerosols of pathogens derived from recombinant DNA methodology is not precluded if a need should arise in the interest of national defense.

One specific program requires special note. The Defense Advanced Research Project Agency is a Pentagon program that invests significantly in pathogen research through grants to qualified institutions. This project initially focused on engineering and electronics (computer) projects; however, starting in 1995 biology became a key focus, and several BW

defensive research grants are now in operation at several academic and private institutions.

Very little is written in the unclassified literature on BW research conducted in countries other than the United States. Great Britain has maintained the Microbiological Research Establishment at Porton Down; however, military research is highly classified in Great Britain and details regarding the research conducted at Porton are unavailable.

During the 1970s and 1980s, much of the U.S. BW policy was based on the assumption of Soviet offensive BW capabilities. Most U.S. accounts of Soviet BW activities were unconfirmed accusations or claims about treaty violations. The Soviet Union was a party to both the 1925 Geneva Protocol and the 1972 BW convention. According to Pentagon sources, the Soviet Union operated at least seven top-security BW centers. These centers were reported to be under strict military control. Although the former Soviet Union proclaimed that their BW program was purely defensive, the United States consistently asserted that the Soviet Union was conducting offensive BW research.

V. CONTEMPORARY ISSUES

A. Genetic engineering

There has been considerable controversy regarding the potential for genetically engineered organisms to serve as effective BW agents. Recombinant DNA technology has been cited as a method for creating novel, pathogenic microorganisms. Theoretically, organisms could be developed that would possess predictable characteristics, including antibiotic resistance, altered modes of transmission, and altered pathogenic and immunogenic capabilities. This potential for genetic engineering to significantly affect the military usefulness of BW has been contested. It has been suggested that because many genes must work together to endow an organism with pathogenic characteristics, the alteration of a few genes with recombinant DNA technology is unlikely to yield a novel pathogen that is significantly more effective or usable than conventional BW agents.

The question of predictability of the behavior of genetically engineered organisms was addressed at an American Society for Microbiology symposium held in June 1985. Some symposium participants believed that the use of recombinant DNA increases predictability because the genetic change can be precisely characterized. Other participants, however, believed that the use of recombinant DNA decreases predictability because it widens the potential range of DNA sources. Other evidence supports the view that genetically engineered

organisms do not offer substantial military advantage over conventional BW. Some studies have shown that in general, genetically engineered organisms do not survive well in the environment. This fact has been cited as evidence that these organisms would not make effective BW agents.

Despite the contentions that genetic engineering does not enhance the military usefulness of BW, a significant number of arguments support the contrary view. At the 1986 review conference of the BW convention, it was noted that genetic engineering advances since the convention entered into force may have made biological weapons a more attractive military option.

Several authors have contended that the question of the potential of genetic engineering to enhance the military usefulness of BW is rhetorical because the 1972 BW convention prohibits development of such organisms despite their origin or method of production. Nations participating in both the 1980 and 1986 review conferences of the BW convention accepted the view that the treaty prohibitions apply to genetically engineered BW agents. An amendment to the treaty, specifically mentioning genetically engineered organisms, was deemed to be unnecessary. In addition, the United States, Great Britain, and the Soviet Union concluded in a 1980 briefing paper that the 1972 BW convention fully covered all BW agents that could result from genetic manipulation.

Although the utility of genetic engineering for enhancing the military usefulness of BW agents has been questioned, the role of genetic engineering for strengthening defensive measures against BW has been clear. Genetic engineering has the potential to improve defenses against BW in two ways: (i) vaccine production and (ii) sensitive identification and detection systems. The issues of the new technologies in defensive research have been evident in the U.S. BW program. Since 1982, U.S. Army scientists have used genetic engineering to study and prepare defenses against BW agents. Military research utilizing recombinant DNA and hybridoma technology includes the development of vaccines against a variety of bacteria and viruses, methods of rapid detection and identification of BW agents, and basic research on protein structure and gene control. By improving defenses against BW, it is possible that genetic engineering may potentially reduce the risk of using BW.

The primary effect of BW on government regulations on genetic engineering is the tendency toward more stringent control of the technologies. The fear of genetically engineered BW agents has prompted proposals for government regulation of BW research utilizing genetic engineering research. The Department of Defense released a statement indicating that all

government research was in compliance with the 1972 BW convention. The government has also prepared an environmental impact statement of research conducted at Fort Detrick.

Government regulations on genetic engineering also affect BW research through limitations on exports of biotechnology information, research products, and equipment. In addition to controls of exports due to competitive concerns of biotechnology companies, a substantial amount of information and equipment related to genetic engineering are prohibited from being exported from the United States. The Commerce Department maintains a "militarily critical technology" list, which serves as an overall guide to restricted exports. Included on the list are containment and decontamination equipment for large production facilities, high-capacity biological reactors, separators, extractors, dryers, and nozzles capable of disseminating biological agents in a fine mist.

Genetic engineering has altered the concept of BW. A current, comprehensive discussion of BW would include both naturally occurring and potential genetically engineered agents. Many current defenses against BW are developed with genetic engineering techniques. Government regulations on biotechnology have limited BW research, while fears of virulent genetically engineered BW agents have strengthened public support for stronger regulations. Future policies related to BW will need to be addressed in light of its altered status.

B. Mathematical epidemiology models

Although genetic engineering may potentially alter characteristics of BW agents, mathematical models of epidemiology may provide military planners with techniques for predicting the spread of a released BW agent. One of the hindrances that has prevented BW from being utilized or even seriously considered by military leaders has been the inability to predict the spread of a BW agent once it has been released into the environment. Without the capability to predict the spread of the released organisms, military planners would risk the accidental exposure of their own troops and civilians to their own weapons. The development of advanced epidemiology models may provide the necessary mechanisms for predicting the spread of organisms that would substantially decrease the deterrent factor of unpredictability.

C. Low-level conflict

Another important factor that has affected the current status of BW is the increase in low-level conflict or the spectrum of violent action below the level of small-scale

conventional war, including terrorism and guerrilla warfare. In the 1980s, the low-intensity conflict doctrine, which was espoused by the Reagan administration, was a plan for U.S. aid to anti-Communist forces throughout the world as a way of confronting the Soviet Union without using U.S. combat troops. Despite the significant changes in the world since the inception of the low-intensity conflict doctrine, the probability of increasing numbers of small conflicts still exists. Although no evidence indicates that the United States would consider violating the 1972 BW convention and support biological warfare, the overall increase in low-level conflicts in the future may help create an environment conducive to the use of BW.

Although BW may not be assessed as an effective weapon in a full-scale conventional war, limited use of BW agents may be perceived as advantageous in a small-scale conflict. Although strong deterrents exist for nuclear weapons, including unavailability and, most formidably, the threat of uncontrolled worldwide "nuclear winter," BW may be perceived as less dangerous. In addition, the participants of low-level conflicts may not possess the finances for nuclear or conventional weapons. BW agents, like chemical weapons, are relatively inexpensive compared to other weapon systems and may be seen as an attractive alternative to the participants and leaders of low-level conflicts. Low-level conflict, therefore, increases the potential number of forums for the use of BW.

D. Terrorism

A final factor that could significantly affect BW is the worldwide increase in terrorism or the violent activities of subnational groups. Although there has not been an incident to date of the successful use of BW by a terrorist group, the possibility of such an event has increased in many forums.

The relationship of terrorism and BW can be divided into two possible events. The first is terrorist acts against laboratories conducting BW-related research. The level of security at Fort Detrick is high, the possibility of a terrorist attack has been anticipated, and contingency plans have been made. Complicating the problem of providing security against terrorist attack in the United States is the fact that although most BW research projects are conducted with the BW research program of the Army, an increasing number of projects are supported by the government that are conducted outside of the military establishment. These outside laboratories could be potential targets.

The second type of terrorist event related to BW is the potential use of BW by terrorists against urban areas or major public facilities. Biological weapons are

relatively inexpensive and easy to develop and produce compared to conventional, nuclear, or chemical weapons. BW agents can be concealed and easily transported across borders or within countries. In addition, terrorists are not hampered by a fear of an uncontrolled spread of the BW agent into innocent civilian populations. On the contrary, innocent civilians are often the intended targets of terrorist activity and the greater chance for spread of the BW agent may be considered to be a positive characteristic (see Section II.C).

E. Offensive versus defensive biological warfare research

The distinctions between “offensive” and “defensive” BW research have been an issue since 1969, when the United States unilaterally pledged to conduct only defensive research. The stated purpose of the U.S. BDRP is to maintain and promote national defense from BW threats. Although neither the Geneva Convention nor the 1972 convention prohibits any type of research, the only research that nations have admitted to conducting is defensive. The problem is whether or not the two types of research can be differentiated by any observable elements.

Although production of large quantities of a virulent organism and testing of delivery systems have been cited as distinguishing characteristics of an offensive program, a substantial amount of research leading up to these activities, including isolating an organism and then using animal models to determine pathogenicity, could be conducted in the name of defense.

Vaccine research is usually considered defensive, whereas increasing the virulence of a pathogen and producing large quantities are deemed offensive. However, a critical component of a strategic plan to use biological weapons would be the production of vaccines to protect the antagonist’s own personnel (unless self-annihilation was also a goal). This means that the intent of a vaccine program could be offensive BW use. Furthermore, research that increases the virulence of an organism is not necessarily part of an offensive strategy because one can argue that virulence needs to be studied in order to develop adequate defense.

The key element distinguishing offensive from defensive research is intent. If the intent of the researcher or the goals of the research program are the capability to develop and produce BW, then the research is offensive BW research. If the intent is to have the capability to develop and produce defenses against BW use, then the research is defensive BW research. Although it is true that nations may have policies of open disclosures (i.e., no secret research), “intent” is not observable.

Although the terms offensive BW research and defensive BW research may have some use in describing intent, it is more a philosophical than a practical distinction—one that is based on trust rather than fact.

F. Secrecy in biological warfare-related research

Neither the Geneva Protocol nor the 1972 BW convention prohibits any type of research, secret or nonsecret. Although the BDRP does not conduct secret or classified research, it is possible that secret BW research is being conducted in the United States outside of the structure of the BDRP. The classified nature of the resource material for this work makes it impossible to effectively determine if secret research is being conducted in the United States or any other nation.

It is not, however, unreasonable to assume that other nations conduct significant secret BW research. Therefore, regardless of the facts, one cannot deny the perception that such research exists in a variety of countries and that this perception will exist for the foreseeable future.

Secrecy has been cited as a cause of decreased quality of BW research. If secret research, whether offensive or defensive, is being conducted in the United States or other nations, it is unclear if the process of secrecy affects the quality of the research. If the secret research process consists of a core of highly trained, creative, and motivated individuals sharing information, the quality of the research may not suffer significantly. It must be stated, however that secrecy by its very nature will limit input from a variety of diverse observers.

Secrecy may increase the potential for violations of the 1972 BW convention; however, violations would probably occur regardless of the secrecy of the research. Secrecy in research can certainly lead to infractions against arbitrary rules established by individuals outside of the research group. The secret nature of the research may lure a researcher into forbidden areas. In addition, those outside of the research group, such as policy-makers, may push for prohibited activities if the sense of secrecy prevails. Secrecy also tends to bind those within the secret arena together and tends to enhance their perception of themselves as being above the law and knowing what is “right.” As in the case of Oliver North and the Iran-Contra Affair, those within the group may believe fervently that the rules must be broken for a justified purpose and a mechanism of secrecy allows violations to occur without penalty.

The distrust between nations exacerbates the perceived need for secret research. The animosity between

the United States and the Soviet Union during the 1980s fueled the beliefs that secret research leading to violations of the 1972 BW convention was being conducted in the Soviet Union. As the belligerence of the 1980s faded into the new world order of the 1990s, the questions focus less on the Soviet Union and more on the Middle East and Third-World countries. There are factions in the United States that believe strongly that other countries are conducting secret research that will lead to violations of the convention. There is also a tendency to believe that the secrecy in one's own country will not lead to treaty violations, whereas the same secret measures in an enemy nation will result in activities forbidden by international law.

The importance of the concept of secrecy in BW research is related to the perception of secrecy and arms control agreements. Regardless of the degree of secrecy in research, if an enemy believes that a nation is pursuing secret research, arms control measures are jeopardized. The reduction of secrecy has been suggested as a tool to decrease the potential for BW treaty violations. A trend toward reducing secrecy in BW research was exemplified by the 1986 review conference of the 1972 BW convention, which resulted in agreements to exchange more information and to publish more of the results of BW research. Whether or not these measures have any effect on strengthening the 1972 BW convention remains to be seen.

Organizations and individuals have urged a renunciation by scientists of all secret research and all security controls over microbiological, toxicological, and pharmacological research. This action has been suggested as a means of strengthening the 1972 BW convention. The belief that microbiologists should avoid secret research is based on the assumption that (i) secret research is of poor quality due to lack of peer review and (ii) secrecy perpetuates treaty violations.

Although it may be reasonable to expect microbiologists to avoid secret research, it is not realistic. Secrecy is practiced in almost every type of research including academic, military, and especially industrial. Furthermore, there will always be those within the military and intelligence structures who believe that at least some degree of secrecy is required for national security.

Secrecy in BW research is a complex issue. The degree to which it exists is unclear. Individuals are generally opposed to secrecy in BW research although other examples of secrecy in different types of research exist. The effect of secrecy on the quality of research, the need for the secrecy, and the choice of microbiologists to participate in secret BW research remain unanswered questions.

G. Problems relating to verification

One of the major weaknesses of the 1972 BW convention has been the lack of verification protocols. Problems with effectively monitoring compliance include the ease of developing BW agents in laboratories designed for other purposes and the futility of inspecting all technical facilities of all nations. Measures that have been implemented with the goal of monitoring compliance included (i) open-inspections, (ii) intelligence gathering, (iii) monitor-research, (iv) use of sampling stations to detect the presence of biological agents, and (v) international cooperation. The progress achieved with the Chemical Weapons Convention has renewed interest in strengthening mechanisms for verification of compliance with the 1972 BW convention. Although this renewed interest in verification along with the emergence of the Commonwealth of Independent States from the old Soviet Union has brought an optimism to the verification issue, the reticence of countries such as Iraq to cooperate with United Nations inspection teams is a reminder of the complexities of international agreements.

The examples discussed in this article are typical of the many issues attached to the concept of BW.

Bioluminescence, Microbial

J. Woodland Hastings

Harvard University

GLOSSARY

autoinducer A homoserine lactone produced by bacteria which, after accumulating in the medium to a critical concentration, initiates transcription of specific genes by a mechanism referred to as autoinduction, recently dubbed **quorum sensing**.

bioluminescence Emission of light by living organisms that is visible to other organisms. It derives from an enzyme-catalyzed chemiluminescence, a highly exergonic reaction in which chemical energy is transformed into light energy.

bioluminescence quantum yield The number of photons produced per luciferin (substrate) molecule oxidized in a bioluminescent reaction.

blue and yellow fluorescent proteins Accessory proteins in the bioluminescence system in some bacteria, carrying lumazine and flavin chromophores, respectively, and serving as secondary emitters under some conditions.

luciferase The generic name for enzymes that catalyze bioluminescent reactions. Luciferases from different major groups of organisms are not homologous (e.g. firefly and jellyfish luciferases are unrelated to bacterial luciferase) so the organism must be specified in referring to a specific luciferase.

luciferin (light bearing) The generic name for a substrate that is oxidized to give light in a bioluminescent reaction; identified as a **flavin** in bacteria and a **tetrapyrrole** in dinoflagellates.

scintillons Bioluminescent organelles unique to dinoflagellates which emit brief bright flashes of light following stimulation.

Bioluminescence is defined as an enzyme-catalyzed chemiluminescence, a chemical reaction in which the energy released is used to produce an intermediate or product in an electronically excited state, which then emits a photon. It does not come from or depend on light absorbed, as in fluorescence or phosphorescence. However, the excited state produced in such a chemical reaction is indistinguishable from that produced in fluorescence after the absorption of a photon by the ground state of the molecule concerned.

All bioluminescent reactions involve the oxidation by molecular oxygen of a substrate by an enzyme, generically referred to as luciferin and luciferase, respectively, with the production of an electronically excited state, typically luciferase bound (Fig. 14.1A). The energy released from the oxidation of a luciferin in such reactions is about 10 times greater than that obtained from the hydrolysis of ATP.

There are numerous (20–30) extant bioluminescent systems, which mostly bear no evolutionary relationships with one another. The many different luciferases are thus considered to have arisen *de novo* and evolved independently, and the luciferins are likewise different. Thus, genes coding for luciferases from fireflies and jellyfish, for example, have no sequence similarities to bacterial or dinoflagellate luciferase, which themselves are unrelated. The luciferases discussed in this article

FIGURE 14.1 (A) Generalized reaction scheme for bioluminescent reactions. (B) The luciferase reaction showing the components involved in the bacterial system. Reduced flavin derived from the electron transport pathway reacts with luciferase and molecular oxygen to form an intermediate peroxide. In a mixed function oxidation with long-chain aldehyde (RCHO), hydroxy-FMN is formed in its excited state (*), from which emission of a photon ($h\nu$) occurs. The FMN and long-chain acid products are recycled.

should therefore be called bacterial luciferase and dinoflagellate luciferase.

I. BACTERIA

A. Occurrence, habitats, species, and functions

In the ocean luminous bacteria occur ubiquitously and can be isolated from most seawater samples from the surface to depths of ~1000 m, and they appear as bright colonies on plates (Fig. 14.2). They are very often found in some kind of symbiotic association with higher organisms (e.g. fish or squid), in which the light emission is evidently of functional importance to the host. In parasitic or saprophytic associations the advantage of light emission accrues more to the bacteria: The light attracts animals to feed, enhancing the

FIGURE 14.2 Colonies of luminous bacteria photographed by their own light (right) and in room light (left). Light is emitted continuously but is controlled by a quorum-sensing mechanism (autoinducer) and is thus not proportional to growth or cell density (Plate 2).

FIGURE 14.3 The flashlight fish (*Photoblepharon*) showing the exposed light organ, which harbors luminous bacteria and is located just below the eye. A special lid allows the fish to turn the light on and off (photograph by Dr. James Morin) (Plate 3).

dispersal of the bacteria. The maximum light emission of a bacterial cell is about 10^4qs^{-1} , meaning that to be seen, the cell density must be high—about 10^9 – 10^{10} cells/ml.

Most luminous bacteria are classed under three major genera—*Vibrio*, *Photobacterium*, and *Photorhabdus*, the first two of which are almost exclusively marine, whereas the last is terrestrial. All are characterized as enteric bacteria and are notable for the symbioses in which they participate, most commonly in light organs in which the light is used by the host for some purpose. The flashlight fish, *Photoblepharon* (Fig. 14.3), maintains cultures of such bacteria in special organs located beneath the eyes. For all luminous bacterial species the primary habitat can be assumed to be in some association, either as a light organ or gut symbiont, or in a parasitic or saprophytic association.

If such associations are viewed as primary habitats, planktonic or “free-living” bacteria in the ocean may be considered secondary or reservoir habitats, produced as overflows or escapees into an environment in which luminescence may not be advantageous and thus not selected for. Thus, the failure, for whatever reason, of the luminescence system to be expressed under these conditions may be advantageous for the survival of the bacteria possessing the genes for luminescence and thus for their ability to compete favorably with heterotrophs not carrying the genes.

Different species occupy different specific habitats. *Vibrio harveyi* is the most cosmopolitan species and is not known to be involved in a light organ symbiosis. It occurs as a gut symbiont in many marine animals, and it is known to parasitize and/or infest saprophytically crustaceans and other species. Fish or squid having specific associations with *Vibrio fischeri*,

Photobacterium phosphoreum, and *Photobacterium leigonathi* as symbionts have been identified, and all of these species have more restricted requirements for growth. Still other symbionts have not been cultured successfully, but affinities and relationships are known from their luciferase DNA sequences.

Photorhabdus luminescens is symbiotic with nematodes, which parasitize caterpillars, where they release the bacteria as an inoculum into the body cavity along with their own fertilized eggs. The bacteria grow, providing nutrient for the developing nematode larvae. The caterpillar does not survive but becomes brightly luminous, possibly to attract animals to feed on it and thereby disperse both nematodes and bacteria. Each young nematode then carries a fresh inoculum, estimated to be about 50–100 bacteria.

B. Biochemistry

1. Light-emitting reaction

Biochemically, light emission results from the luciferase-catalyzed mixed function oxidation of reduced flavin mononucleotide and long-chain aldehyde by molecular oxygen, populating the excited state of a luciferase-hydroxyflavin intermediate, which emits a blue-green light ($\lambda_{\text{max}} \sim 490 \text{ nm}$).

Bacterial luciferase is an α - β heterodimer lacking metals, prosthetic groups, and non-amino acid residues. To date, no sequences in data bases exhibit any similarities to it, so the origin of the gene for the enzyme remains unknown. Although the two subunits are homologous, the active site and the detailed kinetics features of the reaction are properties of the α subunit (singular kinetic).

The reaction represents a biochemical shunt of the respiratory electron transport system, carrying electrons from the level of reduced flavin (FMNH_2) directly to oxygen (Fig. 14.1B). FMNH_2 reacts first with oxygen to form a linear hydroperoxide, which then reacts with long-chain fatty aldehyde to give the postulated peroxyhemiacetal intermediate. This breaks down to give long-chain acid and the intermediate hydroxyflavin in a high-energy electronically excited state. Although aldehydes with chain lengths from 7 to 18 carbon atoms give light in the reaction with isolated luciferase, tetradecanal (14C) has been identified as the naturally occurring molecule in the species studied. While its oxidation provides energy, the aldehyde is not the emitter and is thus not a luciferin, which means “light-bearing.” The flavin is the luciferin in the bacterial system.

One photon is produced for about every four molecules of FMNH_2 oxidized; thus, the bioluminescence

quantum yield is 25%. However, since the fluorescence quantum yield of FMN is about 30%, and the excited state produced as in Fig. 14.1B is equivalent to that which would be produced from light absorption by the hydroxyflavin, it may be concluded that the luciferase reaction is highly efficient.

In the living cell light is produced continuously; the oxidized FMN formed in the reaction is reduced again as indicated in Fig. 14.1B by pyridine nucleotide. Similarly, the myristic acid product is converted back to the corresponding aldehyde by enzymes of a specific fatty acid reductase complex with ATP and NADPH as cofactors.

2. Luciferase structure

The tertiary structure of luciferase (Fig. 14.4) was correctly predicted based on the X-ray crystal structure of a related and homologous protein expressed from *lux F*. The structures of the α and β subunits are similar, differing in a region in which substrate is presumed to bind to the α , although the structure of the site is not known because a determination of the structure with flavin bound has not been made. Both subunits exhibit the so-called $[\beta/\alpha]_8$ barrel form (β/α do not refer to subunits), in which stretches of beta sheet alternate with alpha-helical strands, all of which are parallel to one another, together forming a closed barrel with the eight α helices on the outside. The region of the α subunit where substrate is likely to

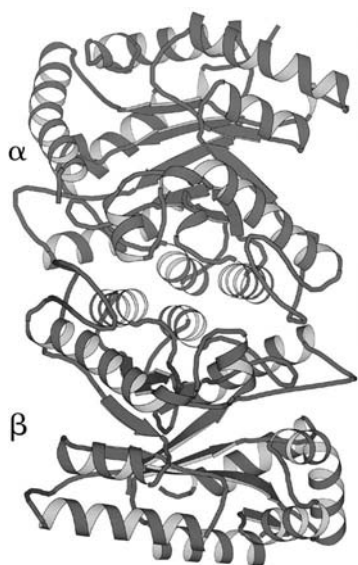

FIGURE 14.4 Ribbon representation of the structure of bacterial luciferase showing the α and β subunits and how they may associate (from Fisher *et al.*, 1995).

bind was not seen in the electron density map, including a region known to be highly sensitive to protease attack that is absent in the β subunit.

3. Antenna proteins: blue and yellow fluorescent proteins as emitters

The basic structure of the luciferase and the biochemistry of the reaction are the same in all luminous bacteria, which typically emit light peaking at about 490 nm. However, in some bacterial strains, the color of the light emitted by the living cell is blue or red shifted, even though the isolated luciferases still peaks at ~490 nm. In a strain of *P. phosphoreum*, the emission is blue shifted, peaking at about 480 nm, whereas in a strain of *V. fischeri* the light is yellow in color ($\lambda_{\max} \sim 540$ nm). In both cases a second ("antenna") protein with its own chromophore is responsible (lumazine and flavin, respectively, for the two cases). The mechanisms involved in these cases have not been fully resolved, but they may be mechanistically similar because the proteins are homologous. Nonradiative energy transfer has been suggested, but evidence indicates that this alone cannot be responsible since the antenna protein appears to actually enter into the light-emitting reaction in the case of the yellow-emitting system. The functional importance for such spectral shifts has not been elucidated, although strains with a blue-shifted emission occur at depths of ~600 m in the ocean.

4. Molecular biology: genes of the lux operon

Lux genes cloned from several different species exhibit sequence similarities indicative of evolutionary relatedness and conservation. In *V. fischeri*, the species most extensively studied, the *lux* operon has five structural and two regulatory genes with established functions. As shown in Fig. 14.5, these include two that code for the α and β subunits of luciferase and three that code for the reductase, transferase, and synthetase components of the fatty acid reductase complex responsible for aldehyde synthesis and reduction and recycling of the acid product. Upstream, in the same operon, is the regulatory gene *lux I*, and immediately adjacent but transcribed in the opposite direction is *lux R*, whose product is responsible for the transcriptional activation of *lux A-E* and others. The latter include *lux F* and *G*, found in some species and located in the same region; these code for proteins whose functions are not well established. However, genes coding for the antenna proteins responsible for color shifting are located elsewhere on the genome but still subject to regulation by the autoinduction mechanism. In luminous *Vibrios* the

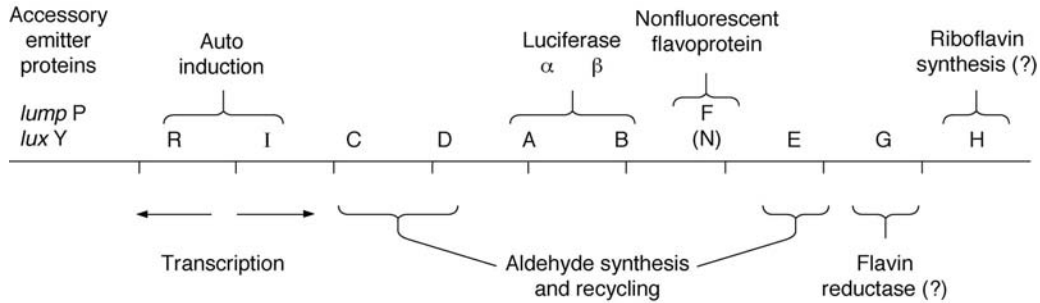

FIGURE 14.5 Organization of the *lux* genes in *Vibrio fischeri*. The operon on the right, transcribed from the 5' to the 3' end, carries genes for synthesis of autoinducer (*lux I*), for luciferase α and β subunits (*lux A* and *B*), and for aldehyde synthesis (*lux C–E*). The operon on the left carries the *lux R* gene, which encodes for a receptor molecule that binds autoinducer; the complex controls the transcription of the right operon. Other genes, *lux F (N)*, *G*, and *H* (right), are associated with the operon but with uncertain functions; genes for accessory emitter proteins also occur (left).

regulatory genes (*lux I* and *R* or their counterparts) are also located remotely from the *lux A–E* operon.

certain specific genes is functionally important only at higher cell densities. The phenomenon was then appropriately dubbed “quorum sensing.”

5. Physiology: regulation of light emission

a. Autoinduction and quorum sensing

Quorum sensing, which was first discovered and referred to as autoinduction in luminous bacteria, refers to a mechanism causing the *lux* genes to be transcribed only at higher cell densities. It is mediated by a homoserine lactone molecule produced by the cells that has been dubbed the autoinducer. In luminous bacteria in a confined environment, such as a light organ, autoinducer can accumulate and act, whereas in free-living bacteria, in which the light could not be seen at the low cell densities, luciferase is of no value and is not produced.

Autoinduction was discovered in the early 1970s and was proposed as an explanation for the fact that luciferase and other components of the light-emitting system are not produced in cells growing at low cell densities but are produced, and rapidly so, above a critical cell concentration (Fig. 14.6). In laboratory cultures subjected to continuous (or repetitive) dilution (maintaining densities lower than $\sim 10^7$ cells/ml), such that autoinducer accumulation is not possible, no synthesis of luciferase or its messenger RNA occurs. The same is true of planktonic populations in the ocean, which are typically at densities of no greater than $\sim 10^2$ cells/ml.

The autoinducer in *V. fischeri* is the product of the *lux I* gene and acts as a positive regulator of the *lux* operon in the presence of a functional *lux R* gene. In the early 1990s it was found that a similar mechanism, also utilizing specific homoserine lactones, occurs in many other diverse groups of bacteria in which expression of

FIGURE 14.6 An experiment demonstrating autoinduction in luminous bacteria. Growth of the cells (measured by optical density at 660 nm) is exponential for the first few hours, during which time there is no change in the bioluminescence or the luciferase content of the culture (arbitrary units). After about 2.5 h, at a cell density of 1 or greater, the *lux* genes are rapidly transcribed and luciferase and other related proteins are synthesized, determined also by reaction with antiluciferase (CRM).

b. Glucose, iron, and oxygen

In both *V. harveyi* and *V. fischeri* luminescence is repressed by glucose, reversible by cyclic AMP. All species except *Photorhabdus luminescens* exhibit induction of luminescence by the addition of iron after growth under conditions of iron limitation, suggesting that eukaryotic hosts might use iron limitation to limit growth while maximizing luminescence of bacterial symbionts.

As a reactant in the luciferase reaction, oxygen can control light emission directly but only at extremely low oxygen concentrations (lower than ~0.1%), above which the luminescence is independent of oxygen. Growth, however, is reduced at concentrations lower than that of air (21%), so growth could be strongly inhibited without affecting the luciferase reaction. Indeed, in some species and strains, transcription of the *lux* operon is greatly favored over growth under microaerophilic conditions, where bright light emission may occur at low cell densities. Regulation by control of oxygen has thus been proposed as a mechanism whereby eukaryotic hosts might control growth of bacterial symbionts in light organs while maximizing luminescence.

In *P. luminescens* grown in pure (100%) oxygen, which is lethal for many bacteria including other luminous species, both luciferase synthesis and luminescence are enhanced in relation to cell mass. It has been proposed that in this case the luciferase system serves to detoxify damaging oxygen radicals.

c. Dark variants

In culture collections it has often been reported that bacteria may lose their luminosity over time in cases in which subculturing care has not been taken to reisolate single bright colonies each time. This can be attributed to the spontaneous occurrence and overgrowth of dark (e.g. very dim) variants, which in some ways appear to be similar to phase variants reported in other groups of bacteria. These dark variants do not produce luciferase or other luminescence components and are pleiotropic, being altered in several other properties such as cell morphology and phase sensitivity.

Dark variants could presumably provide a genetic mechanism whereby cells could respond to environmental conditions that select for or against the property of luminescence. Although such conditions have not been established, this would allow cells to compete better with other heterotrophic bacteria under conditions where luminescence is of no use and thereby become more widely dispersed but prepared to populate a niche where luminescence is functionally important.

II. DINOFLAGELLATES

A. Occurrence, habitats, species, and functions

Ocean "phosphorescence," commonly seen at night (especially in summer) when the water is disturbed, is due in large part to the bioluminescence of dinoflagellates. The organisms occur ubiquitously in the oceans as planktonic forms and respond to mechanical stimulation when the water is disturbed, such as by waves or fish swimming, by emitting brief (~0.1 s) bright flashes (~ 10^9 photons each). The wake of a large ship may be evident from such light emission for approximately 20 miles. Luminescent dinoflagellates occur primarily in surface waters and many species are photosynthetic. Only approximately 20–30% of marine species are bioluminescent.

The so-called red tides are transient blooms (usually for weeks) of individual dinoflagellate species. Cells typically migrate vertically during the night to deeper water where available nutrients are taken up, returning to the surface to photosynthesize during the day. Phosphorescent bays (e.g. in Puerto Rico and Jamaica) are persistent blooms of this type; in Puerto Rico, the dominant species is *Pyrodinium bahamense*.

As a group, dinoflagellates are important as symbionts, notably for contributing photosynthesis and carbon fixation in certain animals. Unlike bacteria, however, luminous dinoflagellates are not known to be harbored as symbionts on the basis of their light emission.

Since dinoflagellates are stimulated to emit light when predators (e.g. crustaceans) are active, predators might thereby be alerted to feed on crustaceans, resulting in a reduced predation on dinoflagellates generally. Predation on dinoflagellates may also be impeded more directly and help individual cells. The flash could startle or divert a predator, allowing that cell to escape predation. The response time to stimulation (milliseconds) is certainly fast enough to have this effect. This latter explanation, though supported by experiment, does not easily account for the fact that not all species are bioluminescent.

B. Cell biology

Luminescence in dinoflagellates is emitted from many small (~0.5 μm) cortical locations (Fig. 14.7). The structures have been identified as a new type of organelle termed scintillons (flashing units). They occur as out-pocketings of the cytoplasm into the cell vacuole, like a balloon, with the neck remaining connected. Scintillons contain only dinoflagellate luciferase and

FIGURE 14.9 Bioluminescent flashes and glow of *Gonyaulax*. (A) Oscilloscope trace (ordinate, light intensity; abscissa, time, 8 s) recording from a vial with 32 000 cells. Six flashes having durations of about 100 ms are superimposed on a background glow. (B) Recording for 5 days from a similar vial kept in constant conditions showing the circadian rhythm of the background glow. The frequency of flashing also exhibits a circadian rhythm (not shown).

continue to exhibit rhythmicity (Fig. 14.9B), but with a period that is not exactly 24 h—it is only about (*circa*) 1 day (*diem*) (thus the origin of the term).

Genes coding for molecular components of the circadian clock have been identified and studied in several systems, and a mechanism involving negative feedback on the transcription of a gene by its protein product is postulated to be responsible for the rhythm. How such a mechanism might exert physiological control is not understood. In humans and other higher animals, in which it regulates the sleep–wake cycle and many other physiological processes, the mechanism involves the nervous system. However, it also occurs in plants and unicellular organisms, such as *G. polyedra*, in which daily changes in the cellular concentrations of luciferase, luciferin, and its binding protein occur. The two proteins are synthesized and destroyed each day,

as are the scintillons in which they are located. Hence, the biological clock exerts control at a very basic level by controlling gene expression. This might explain the greater amount of luminescence at night, but a biochemical basis for the increased sensitivity to mechanical stimulation is not evident.

III. FUNGI

A. Occurrence, habitats, species, and functions

Light emission now known to be due to fungi has been observed since ancient times and was noted by both Aristotle and Pliny. Robert Boyle placed “shining wood” in his vacuum apparatus and showed that light emission was reversibly extinguished by the removal of

air, anticipating the requirement for molecular oxygen by all bioluminescent systems. Definitive knowledge of the fungal origin of luminous wood emerged during the nineteenth century from extensive studies of timbers used for support in mines, and by the mid-twentieth century about 80 luminous species had been inventoried. As in bacteria, the emission is continuous and not affected by mechanical stimulation, but it is really quite dim. There is no indication that luminescence is regulated in relation to cell growth or density, but there is some evidence that nutrition may play a role. There have been reports that the luminescence is circadian regulated, as in dinoflagellates, but such results have not been confirmed or extended.

With one possible exception, all luminous fungi are basidiomycetes, and most are in the mushroom family; both the mycelium and fruiting body are luminous (Fig. 14.10). Such fungi occur in the many diverse habitats in which fungi occur, with the luminescence being visible most readily in dark forests—both tropical and temperate. The most striking reports describe luminescence from the interior or an infested tree split open by lightning.

The function of bioluminescence in fungi is not well understood. It has been suggested that the light serves as an attractant, which is consistent with the generalization that a continuous light emission acts in this way. If so, insects or other invertebrates might be attracted and enhance spore dispersal. However, this leaves the function of emission in the mycelium unexplained. The system might have evolved biochemically without constraints regarding its localization, and since it is probably not an energy-intensive function its value in any part of the lifecycle could be adequate to justify its retention.

FIGURE 14.10 Bioluminescent mushroom photographed by its own light (photograph by Dr. Dan Perlman) (Plate 5).

B. Biochemistry

The spectrum of the light emitted has been determined from several species, all of which peak at about 525 nm, consistent with a flavin emitter. However, no biochemical evidence indicates this, and indeed no satisfactory understanding of the chemical basis for light emission has been obtained. Many years ago, a luciferin–luciferase-type system was reported with a link to reduced pyridine nucleotide, comparable to the bacterial system. However, this has not been confirmed in more recent studies, which suggest that the reaction may be a nonenzymatic chemiluminescence.

Bioreactors

Larry E. Erickson

Kansas State University

GLOSSARY

airlift reactor Column with defined volumes for upflow and downflow of the culture broth; vertical circulation occurs because air is bubbled into the upflow volume.

batch bioreactor Culture broth is fed into the reactor at the start of the process; air may flow continuously.

bubble reactor Aerated column without mechanical agitation.

fed batch Liquid media is fed to the reactor continuously; the broth accumulates in the reactor because there is no outflow of liquid.

heterotrophs Microorganisms growing on an organic compound that provides carbon and energy.

insect cell culture Cultivation of insect cells in a bioreactor to produce a protein or other product.

photoautotrophs Microorganisms that use light for energy and carbon dioxide for their carbon source.

plant cell culture Production of plant cells in a bioreactor to produce useful products.

protein engineering The design, development, and production of new protein products with properties of commercial value.

tissue engineering The design, development, and production of tissue cells (biomaterials) for use on or in humans.

Bioreactors are vessels or tanks in which whole cells or cell-free enzymes transform raw materials into biochemical products and/or less undesirable byproducts. The microbial

cell is a miniature bioreactor; other examples include shake flasks, petri dishes, and industrial fermentors. Diagnostic products based on enzymatic reactions, farm silos for silage fermentations, bread pans with fermenting yeast, and the soil in a Kansas wheat field may also be viewed as bioreactors. Although the bioreactor may be simple or highly instrumented, the important consideration is the ability to produce the desired product or result. The bioreactor is designed and operated to provide the environment for product formation selected by the scientist, baker, or wine-maker. It is the heart of many biotechnological systems that are used for agricultural, environmental, industrial, and medical applications.

I. INTRODUCTION

The importance of the bioreactor is recorded in early history. The Babylonians apparently made beer before 5000 BC. Wine was produced in wineskins, which were carefully selected for their ability to produce a beverage that met the approval of the king and other members of his sensory analysis taste panel. Food and beverage product quality depended on art and craftsmanship rather than on science and engineering during the early years of bioreactor selection and utilization. Early recorded history shows that some understood the importance of the reactants and the environmental or operating conditions of the reactor. This allowed leavened bread and cheese to be produced in Egypt more than 3000 years ago.

The process of cooking food to render it microbiologically safe for human consumption and to improve its sensory qualities is also an ancient tradition. The process of thermal inactivation of microorganisms through the canning of food to allow safe storage was an important early achievement in bioreactor design and operation.

As humans learned to live in cities, waste management including wastewater treatment became a necessity for control of disease. One of the first process engineering achievements was the biological treatment of wastes in bioreactors designed and built by humans for that purpose. Because a significant fraction of the population of a city could die from disease spread by unsanitary conditions, these early bioreactors represented important advancements.

After microorganisms were discovered, microbiologists and engineers increased their understanding of the biochemical transformations in bioreactors. Simple anaerobic fermentations for the production of ethyl alcohol, acetone, and butanol were developed. Aerobic and anaerobic treatment of waste-water became widely used. Sanitary engineering became a part of civil engineering education.

In the 1940s, the field of biochemical engineering emerged because of developments in the pharmaceutical industry that required large-scale bioreactors for the production of streptomycin and penicillin. Progress in bioreactor design and control resulted from research on oxygen transfer, air and media sterilization, and pH control. The central concern of the early biochemical engineers was the development of bioreactors that could achieve and maintain the chemical and physical environment for the organism that the biochemist/microbiologist recommended. The ability to scale-up from laboratory bioreactors to large fermentors required the development of instrumentation such as the sterilizable oxygen electrode. Early courses in biochemical engineering were concerned with the analysis, design, operation, and control of bioreactors. Although the field of biochemical engineering is less than 60 years old and some of the pioneers are still available to provide a first-person account of those exciting days, great progress has been made in bioreactor engineering. Some of the significant developments in bioreactor technology and their approximate dates are listed in Table 15.1.

II. CLASSIFICATIONS OF BIOREACTORS

Several methods have been used to classify bioreactors, including the feeding of media and gases and the

TABLE 15.1 Significant developments in bioreactor technology

Development	Year ^d

withdrawal of products; the mode of operation may be batch, fed batch, or continuous. The classification may be based on the electron acceptor; the design may be for aerobic, anaerobic, or microaerobic conditions. In aerobic processes, the methods of providing oxygen have resulted in mechanically agitated bioreactors, airlift columns, bubble columns, and membrane reactors. The sterility requirements of pure culture processes with developed strains differ from those of environmental mixed-culture processes, which are based on natural selection. In some bioreactors the vessel is made by humans and there are also natural bioreactors, such as the microbial cell, the flowing river, and the field of native grass. In this article, the classification of bioreactors is based on the physical form of the reactants and products.

A. Gas phase reactants or products

Oxygen and carbon dioxide are the most common gas phase reactants and products; others include hydrogen, hydrogen sulfide, carbon monoxide, and methane. Oxygen is a reactant in aerobic heterotrophic growth processes, whereas it is a product in photoautotrophic growth. Generally, the concentration of the

reactants and products in the liquid phase in the microenvironment of the cell influences the kinetics of the cellular reaction. Mass transfer to and from the gas phase affects bioreactor performance in most processes with gas phase reactants or products. The anaerobic reactor is designed to exclude oxygen. In some cases, inert gases are bubbled into the anaerobic reactor to provide a gas-liquid interfacial area to remove the product gases.

Because the solubility of oxygen in water is very low, the dissolved oxygen in the broth is rapidly depleted if oxygen transfer from the gas to the liquid phase is disrupted in aerobic processes. The distribution of dissolved oxygen throughout the reactor volume and the transient variation affect reactor performance. When mold pellets or biofilms are present, the diffusion of oxygen into the interior should be considered. A significant portion of the bioreactor literature is devoted to oxygen transfer and the methods recommended for the design and operation of aerobic bioreactors. The phase equilibrium relationship is based on thermodynamic data, whereas the rate of oxygen transfer depends on the gas-liquid interfacial area and the concentration driving force. Mechanical agitation increases the gas-liquid interfacial area. Aeration provides the supply of oxygen, and it affects the gas-liquid interfacial area.

Oxygen has been supplied by permeation through membranes in cultures in which bubbles may damage shear-sensitive cells. The membrane area and concentration driving force determine the oxygen transfer rate in these bioreactors.

Most large-scale bioreactors have either oxygen or carbon dioxide among the reactants or products. In many anaerobic fermentations the formation of carbon dioxide results in bubbling, and often no additional mixing is required for either mass transfer or suspension of the microbial cells. Methane is produced through anaerobic digestion of waste products. It is also a product of microbial action in landfills, bogs, and the stomach of the cow.

Packed-bed bioreactors are used to biodegrade volatile organic compounds in air pollution control applications. The rhizosphere provides a natural environment in which many volatile compounds in soil are transformed by microbial and plant enzymes.

B. Liquid phase reactants or products

Many bioreactors have liquid phase reactants and products. Ethanol, acetone, butanol, and lactic acid are liquid products that can be produced by fermentation. The kinetics of biochemical reactions depends on the liquid phase concentrations of the reactants

and, in some cases, the products. The Monod kinetic model and the Michaelis-Menten kinetic model show that many biochemical reactions have first-order dependence on reactant (substrate) concentration at low concentrations and zero-order dependence at higher concentrations. Rates are directly proportional to concentrations lower than 10 mg/liter for many reactants under natural environmental conditions. At very high concentrations, inhibition may be observed.

Hydrocarbons that are relatively insoluble in the water phase, such as hexadecane, may also be reactants or substrates for biochemical reactions. Microbial growth on hydrocarbons has been observed to occur at the liquid-liquid interface and in the water phase. The oxygen requirements are greater when hydrocarbon substrates are used in place of carbohydrates. In the past, there was great interest in the production of microbial protein from petroleum hydrocarbons. The commercialization of the technology was most extensive in the former Soviet Union. The airlift bioreactor is uniquely suited for this four-phase process because of the tendency of the hydrocarbon phase to migrate to the top of the fermentor. The hydrocarbons are found suspended as drops in the water phase, adsorbed to cells, and at the gas-liquid interface. The cells are found adsorbed to hydrocarbon drops, suspended in the water phase, and at the gas-liquid interface. In the airlift fermentor, the vertical circulation mixes the hydrocarbons and cells that have migrated to the top of the fermentor with the broth that enters the downflow side of the column.

One of the oldest and most widely practiced fermentations is the microbial production of ethanol and alcoholic beverages such as beer and wine. Because ethanol inhibits fermentation at high concentrations, the process of inhibition has been extensively studied for this fermentation. Ethanol affects the cell membrane and the activities of enzymes. This inhibition limits the concentration of ethanol that can be obtained in a fermentor. Because ethanol is also produced for use as a motor fuel, there is still considerable research on ethanol production. Because the cost of the substrate is a major expense, inexpensive raw materials such as wastes containing cellulose have been investigated.

C. Solid phase reactants or products

There are many examples of bioreactors with solid phase reactants. The cow may be viewed as a mobile bioreactor system that converts solid substrates to methane, carbon dioxide, milk, and body protein. Although the cow is a commercial success, many

efforts to transform low-cost cellulosic solid waste to commercial products in human-made bioreactors have not achieved the same level of success.

Solid substrates such as soybean meal are commonly fed into commercial fermentations. Through the action of enzymes in the fermentation broth, the biopolymers are hydrolyzed and more soluble reactants are obtained.

Many food fermentations involve the preservation of solid or semisolid foods such as in the conversion of cabbage to sauerkraut and meats to sausage products. Cereals, legumes, vegetables, tubers, fruits, meats, and fish products have been fermented. Some fermented milk processes result in solid products such as cheeses and yogurts.

Other examples include the composting of yard wastes, leaching of metals from ores, silage production, biodegradation of crop residues in soil, microbial action in landfills, and the remediation of contaminated soil.

In many of these fermentations, mixing is difficult or expensive. Transport of essential reactants may depend on diffusion; the concentrations of reactants and products vary with position. Rates may be limited by the transport of essential reactants to the microorganisms.

Most compounds that are present as solids in bioreactors are somewhat soluble in the water phase. For reactants that are relatively insoluble, biochemical reaction rates may be directly proportional to the available interfacial area. The surface of the solid may be the location of the biochemical transformation. An example of microorganisms growing on the surface of a solid substrate is mold on bread. To design bioreactors for solid substrates and solid products, the solubility and the transport processes should be considered as well as the kinetics of the process.

Recently, there has been considerable progress in tissue engineering. The rational design of living tissues and the production of these tissues by living cells in bioreactors are advancing rapidly because of progress in systems design and control for both *in vitro* flow reactors and *in vivo* maintenance of cell mass.

D. Microorganisms in bioreactors

The rate of reaction in bioreactors is often directly proportional to the concentration of microbial biomass. In biological waste treatment, the influent concentration of the organic substrate (waste) is relatively low, and the quantity of microbial biomass that can be produced from the waste is limited. The economy of the operation and the rate of biodegradation are enhanced by retaining the biomass in the bioreactor.

In the activated sludge process, this is done by allowing the biomass to flocculate and settle; it is then recycled. The trickling filter retains biomass by allowing growth on the surfaces of the packing within the bioreactor.

A variety of immobilized cell reactors and immobilized enzyme reactors have been designed and operated because of the economy associated with reuse of cells and enzymes. In the anaerobic production of ethanol, lactic acid, and the other fermentation products, the product yield is greatest when the organisms are not growing and all the substrate is being converted to products. Continuous processes can be designed in which most of the cells are retained and the limiting maximum product yield is approached. Ultra-filtration membrane bioreactors have been used to retain cells, enzymes, and insoluble substrates.

In nature, cells are retained when biofilms form along flow pathways. The biofilms allow microorganisms to grow and survive in environments in which washout would be expected. The excellent quality of groundwater is the result of microbial biodegradation and purification under conditions in which microbial survival is enhanced by biofilm formation and cell retention on soil and rock surfaces. The ability of microorganisms to survive even after their food supply appears to be depleted is well established; this is the reason that there are microorganisms almost everywhere in nature. When spills occur, organic substances will often be degraded by microorganisms, if the nutritional environment is balanced. Nitrogen, phosphorous, and other inorganic nutrients often must be added.

The concentration of cells adsorbed to the surface and the concentration in the water phase depends on an adsorption phase equilibrium relationship and the operating conditions. In many environmental applications, most of the cells are adsorbed to surfaces. However, in large-scale fermentors with high cell concentrations and rich media feeds, only a small fraction of the cells are found on surfaces.

E. Photobioreactors

Light is the energy source that drives photoautotrophic growth processes. Because light is absorbed by the growing culture, the intensity decreases rapidly as the distance from the surface increases. Photobioreactors are designed to produce the quantity of product that is desired. Heat transfer is an important design aspect because any absorbed light energy that is not converted to chemical energy must be dissipated as heat.

III. PRINCIPLES OF BIOREACTOR ANALYSIS AND DESIGN

The basic principles of bioreactor analysis and design are similar to those for chemical reactors; however, many biochemical processes have very complex biochemistry. The chemical balance equations or stoichiometry of the process must be known or investigated. The yield of microbial biomass and products depends on the genetics of the strain and the operating conditions. The consistency of data from experimental measurements can be evaluated using mass balances such as the carbon balance and the available electron balance.

Microorganisms obey the laws of chemical thermodynamics; some heat is produced in heterotrophic growth processes. The free energy change is negative for the complete system of biochemical reactions associated with heterotrophic growth and product formation. Thus, the chemical energy available for growth and product formation decreases as a result of microbial assimilation of the reactants.

The rate of growth and product formation depends on the number of microorganisms and the concentrations of the nutrients. The kinetics of growth and product formation is often written in terms of the concentration of one rate-limiting substrate; however, in some cases, more than one nutrient may be rate limiting. The kinetics must be known for rational design of the bioreactor.

Heat is evolved in microbial bioreactors. For aerobic processes, the quantity of heat generated (heat of fermentation) is directly proportional to the oxygen utilized. Thus, the heat transfer and oxygen transfer requirements are linked by the energy regularity of approximately 450 kJ of heat evolved per mole of oxygen utilized by the microorganisms.

Transport phenomena is widely applied in bioreactor analysis and design. Many fermentation processes are designed to be transport limited. For example, the oxygen transfer rate may limit the rate of an aerobic process. Bioreactor design depends on the type of organism and the nutritional and environmental requirements. For example, in very viscous mycelial fermentations, mechanical agitation is often selected to provide the interfacial area for oxygen transfer. Likewise, animal cells that grow only on surfaces must be cultured in special bioreactors, which provide the necessary surface area and nutritional environment. In other cases, animals are used as the bioreactors because the desired biochemical transformations can best be achieved by competitively utilizing animals; cost and quality control are both important when food and pharmaceutical products are produced.

IV. SENSORS, INSTRUMENTATION, AND CONTROL

The ability to measure the physical and chemical environment in the fermentor is essential for control of the process. In the past 50 years, there has been significant progress in the development of sensors and computer control. Physical variables that can be measured include temperature, pressure, power input to mechanical agitators, rheological properties of the broth, gas and liquid flow rates, and interfacial tension. The chemical environment is characterized by means of electrodes for hydrogen ion concentration (pH), redox potential, carbon dioxide partial pressure, and oxygen partial pressure. Gas phase concentrations are measured with the mass spectrometer. Broth concentrations are measured with gas and liquid chromatography; mass spectrometers can be used as detectors with either gas or liquid chromatography. Enzyme thermistors have been developed to measure the concentrations of a variety of biochemicals. Microbial mass is commonly measured with the spectrophotometer (optical density) and cell numbers through plate counts and direct microscopic observation. Instruments are available to measure components of cells such as reduced pyridine nucleotides and cell nitrogen. On-line biomass measurements can be made using a flow cell and a laser by making multi-angle light scattering measurements. Multivariate calibration methods and neural network technology allow the data to be processed rapidly and continuously such that a predicted biomass concentration can be obtained every few seconds.

The basic objective of bioreactor design is to create and maintain the environment that is needed to enable the cells to make the desired biochemical transformations. Advances in instrumentation and control allow this to be done reliably.

V. METABOLIC AND PROTEIN ENGINEERING

Genetic modification has allowed many products to be produced economically. With the use of recombinant DNA technology and metabolic engineering, improved cellular activities may be obtained through manipulation of enzymatic, regulatory, and transport functions of the microorganism. The cellular modifications of metabolic engineering are carried out in bioreactors. Successful manipulation requires an understanding of the genetics, biochemistry, and physiology of the cell. Knowledge of the biochemical

pathways involved, their regulation, and their kinetics is essential.

Living systems are bioreactors. Through metabolic engineering, man can modify these living bioreactors and alter their performance. Metabolic engineering is a field of reaction engineering that utilizes the concepts that provide the foundation for reactor design, including kinetics, thermodynamics, physical chemistry, process control, stability, catalysis, and transport phenomena. These concepts must be combined with an understanding of the biochemistry of the living system. Through metabolic engineering, improved versions of living bioreactors are designed and synthesized.

Although many products are produced in microbial cells, other cell lines, including insect cells, mammalian cells, and plant cells, are utilized for selected applications. The science to support these various living bioreactors is growing rapidly and the number of different applications is increasing steadily. The choice of which organism to select for a specific product must be made carefully, with consideration of biochemistry, biochemical engineering, safety, reliability, and cost. Both production and separation processes affect the cost of the product; however, the costs of product development, testing, regulatory approval, and marketing are also substantial.

Proteins with specific functional properties are being designed, developed, and produced through applications of protein engineering. Through molecular modeling and computer simulation, proteins with specific properties are designed. Protein production may involve applications of recombinant DNA technology in host cell expression bioreactors. An alternative is the production of a protein with the desired amino acid sequence through direct chemical synthesis.

VI. STABILITY AND STERILIZATION

Although beneficial genetic modification has led to many successful industrial products, contamination and genetic mutations during production operations have resulted in many batches of useless broth. Batch processes are common in bioreactors because of the need to maintain the desired genetic properties of a strain during storage and propagation. Continuous operation is selected for mixed-culture processes such as wastewater treatment, in which there is natural selection of effective organisms.

Bioreactors that are to operate with pure cultures or mixed cultures from selected strains must be free of contamination; i.e., the reactor and associated instrumentation must be sterilizable. The vessels that

are to be used for propagation of the inoculum for the large-scale vessel must also be sterilizable. Methods to sterilize large vessels, instrumentation, and connecting pipes are well developed; however, there is a continuous need to implement a wide variety of good manufacturing practice principles to avoid contamination problems.

Steam sterilization has been widely applied to reduce the number of viable microorganisms in food and in fermentation media. As temperature increases, the rates of biochemical reactions increase exponentially until the temperature affects the stability of the enzyme or the viability of the cell. The Arrhenius activation energies, which have been reported for enzymatic reactions and rates of cell growth, are usually in the range of 20–80 kJ/g/mol, whereas activation energies for the thermal inactivation of microorganisms range from 200 to 400 kJ/g/mol. Many of the preceding principles also apply to the thermal inactivation of microorganisms in bioreactors. When solids are present in foods or fermentation media, heat transfer to the interior of the solids occurs by conduction. This must be considered in the design of the process because of the increase in the required sterilization time.

VII. CONCLUSIONS

Bioreactors are used for a variety of purposes. The knowledge base for their application has increased significantly because of the advances in chemical, biochemical, and environmental engineering during the past 60 years.

Bioremediation

Joseph B. Hughes, C. Nelson Neale, and C. Herb Ward

Rice University

GLOSSARY

bioattenuation The nonengineered, natural decomposition of organic contaminants in soil and groundwater systems.

biochemical markers Easily monitored (e.g., substrate-specific microbial population) or chemical (e.g., metabolic intermediates and end products) indicators of biodegradation or biotransformation.

biodegradation Metabolism of a substance by microorganisms that yields mineralized end products.

bioslurry treatment Accelerated biodegradation of contaminants by the suspension of contaminated soil or sediment in water through mixing energy.

biotransformation Microbially mediated process in which the original compound is converted to secondary or intermediate products.

bioventing Accelerated biodegradation of contaminants in contaminated subsurface materials by forcing and/or drawing air through the unsaturated zone.

cometabolism Fortuitous metabolism of a compound by a microorganism that neither yields energy directly nor produces a metabolic product that can subsequently be involved in energy metabolism.

composting Accelerated biodegradation of contaminants at high temperatures by aerating and adding bulking agents and possibly nutrients to waste in a compost pile.

ex situ bioremediation Biological treatment of excavated or removed contaminated media.

immobilization Chemical and/or physical processes by which contaminants become strongly associated or sorbed with a soil matrix or sludge and desorption is limited.

in situ bioremediation Treatment without physical disruption or removal of contaminated media.

land treatment Accelerated biodegradation of contaminated media through application to surface soils to enhance aeration and, in some cases, to allow for nutrient amendment.

microcosm Highly controlled laboratory-scale apparatus used to model or simulate the fate or transport of compounds under the biological, chemical, and physical conditions found in the natural environment.

plume Dissolved contaminants emanating from a source region due to groundwater transport processes.

unsaturated zone Region which spans the area located just beneath the surface and directly above the water table.

Bioremediation is defined in this article as the process by which microorganisms are stimulated to rapidly degrade hazardous organic contaminants to environmentally safe levels in soils, sediments, subsurface materials, and groundwater. Biological remediation processes have also recently been devised to either precipitate or effectively immobilize

inorganic contaminants such as heavy metals; however, treatment of inorganic contaminants will not be included in this definition of bioremediation. Stimulation is achieved by the addition of growth substrates, nutrients, terminal electron acceptor, electron donors, or some combination therein, resulting in an increase in contaminant biodegradation and biotransformation. The microbes involved in bioremediation processes may obtain both energy and carbon through the metabolism of organic contaminants. In some cases, metabolism occurs via a cometabolic process or by a terminal electron-accepting process. Independent of the metabolic pathways, bioremediation systems are designed to degrade hazardous organic contaminants sorbed to soils and sediments or dissolved in water. Bioremediation of contaminants may occur *in situ* or within the contaminated soil, sediments, or groundwater. Alternatively, the contaminated media may be removed and treated using *ex situ* techniques.

I. INTRODUCTION

With the advent of petroleum refining and manufacture of synthetic chemicals, many potentially hazardous organic compounds have been introduced into the air, water, and soil. One method for removing these undesirable compounds from the environment is bioremediation, an extension of carbon cycling. Given the appropriate organism(s), time, and growth conditions, a variety of organic compounds, such as oil and petroleum products, creosote wastes, and a variety of synthetic organic chemicals, can be metabolized to innocuous materials, usually carbon dioxide (CO₂), water, inorganic salts, and biomass (mass of bacterial cells); however, metabolic byproducts, some of which are undesirable, may accumulate when biodegradation of compounds is incomplete. Bioremediation is normally achieved by stimulating the indigenous microflora (naturally occurring microorganisms) present in or associated with the material to be treated. In instances in which the indigenous microflora fails to degrade the target compounds or has been inhibited by the presence of toxicants, microorganisms with specialized metabolic capabilities may be added (bioaugmentation).

The technical basis for modern bioremediation technology has a very long history (e.g., composting of organic wastes into mulch and soil conditioners). Bioremediation technology has grown to include the biological treatment of sewage and wastewater, food processing wastes, agricultural wastes, and, recently, contaminants in soils and groundwater. In this article, bioremediation is defined and limited to the biological treatment of organic contaminants. First, we present

important background information on the metabolic processes that drive bioremediation, the requirements for the stimulation of specific metabolic processes, and the influence of contaminant behavior and distribution on contaminant availability for microbial uptake. This discussion is followed by sections outlining favorable growth conditions for microorganisms that are capable of degrading common classes of organic contaminants found in soil, sediments, and groundwater. Engineered systems used for the treatment of contaminated media are then presented.

II. BACKGROUND SCIENCES

The following two sections describe the fundamental metabolic processes that govern bioremediation as well as biodegradation and biotransformation characteristics of selected classes of organic contaminants. A more thorough treatment of the subject matter may be found in many texts and monographs, and the reader is encouraged to consult these materials for further information. Some of the more notable and recent references include *Microbial Transformation and Degradation of Toxic Organic Chemicals* (Young and Cerniglia, 1994), *Biological Degradation and Bioremediation of Toxic Chemicals* (Chaudry, 1994), *Biodegradation and Bioremediation* (Alexander, 1994), *Biology of Microorganisms* (Madigan *et al.*, 1997), and *Biodegradation of Nitroaromatic Compounds* (Spain, 1995).

A. Metabolic processes

The metabolism of organic contaminants can be broadly differentiated by the ability of the organisms to gain energy for cell growth from the process. If the metabolism of a compound provides energy for cell maintenance and division, the contaminant is referred to as a primary substrate. In some cases, a compound is metabolized and provides the cell with energy but does not support growth. Contaminants of this type are referred to as secondary substrates. If a compound is transformed without benefit of the cell (no energy or carbon provided for use by the organism) while the cell is obtaining energy from another transformable compound, the biotransformation is referred to as cometabolic. Finally, an additional classification has been recently identified in which some contaminants are capable of serving as the terminal electron acceptor in the respiratory chain of certain anaerobic (without oxygen) bacteria. In this case, energy is not obtained from the contaminant itself, but its transformation is a component of metabolic processes that provide energy to the cell for growth.

B. Growth requirements

An essential element of bioremediation processes is the ability to sustain enhanced levels of metabolic activity for extended periods of time. To accomplish this objective, an assessment of conditions at contaminated sites is conducted to determine limiting factors that will be manipulated in an engineered process. A comprehensive list of considerations in this assessment is provided in Table 16.1. For naturally occurring organic compounds (i.e., petroleum hydrocarbons), the availability of oxygen as an electron acceptor is often the primary limiting factor. This can be demonstrated through an evaluation of the stoichiometry of hydrocarbon mineralization, as is shown here for benzene or C₆H₆ (a common contaminant of concern at sites at which gasoline has been spilled):

For the complete mineralization of 1 mol of C₆H₆, 7.5 mol of oxygen will be consumed. Water, in equilibrium with the atmosphere, contains approximately 8 mg/liter dissolved oxygen, which can support the oxidation of 2.6 mg/liter C₆H₆. Since the solubility of

C₆H₆ in water is approximately 1800 mg/liter, the availability of oxygen limits the extent to which hydrocarbons may be biodegraded.

C. Bioaugmentation

For contaminant metabolism to occur in a bioremediation system, organisms with the genetic capacity to transform compounds of interest must be present. Experience has demonstrated that this is often the case in media in which contamination has been present for even short time periods. In certain cases, the addition of organisms acclimated to specific contaminants, or bioaugmentation, may decrease the duration of lag phases. The ability to effectively bioaugment bioremediation systems is a function of the process used. Bioaugmentation is best suited for processes in which contaminated soil or sediments have been excavated and can be mixed or tilled. The bioaugmentation of *in situ* processes is more difficult because of difficulties in uniformly distributing cells throughout a porous medium. Few cases exist in which bioaugmentation of contaminated groundwater aquifers has proven beneficial.

TABLE 16.1 Requirements for microbial growth in bioremediation processes

Requirement	Description
Carbon source	Carbon contained in many organic contaminants may serve as a carbon source for cell growth. If the organism involved is an autotroph, CO ₂ or HCO ₃ ⁻ in solution is required. In some cases, contaminant levels may be too low to supply adequate levels of cell carbon, or the contaminant is metabolized via cometabolism. In these cases the addition of carbon sources may be required.
Energy source	In the case of primary metabolism, the organic contaminant supplies energy required for growth. This is not the case when the contaminant is metabolized via secondary metabolism or cometabolism or as a terminal electron acceptor. If the contaminant does not serve as a source of energy, the addition of a primary substrate(s) is required.
Electron acceptor	All respiring bacteria require a terminal electron acceptor. In some cases, the organic contaminant may serve in this capacity. Dissolved oxygen is a common electron acceptor in aerobic bioremediation processes. Under anaerobic conditions, NO ₃ ⁻ , SO ₄ ²⁻ , SO ₂ ⁺ and CO ₂ may serve as terminal electron acceptors. Certain cometabolic transformations are carried out by fermentative and other anaerobic organisms, in which terminal electron acceptors are not required.
Nutrients	Nitrogen (ammonia, nitrate, or organic nitrogen) and phosphorus (<i>ortho</i> -phosphate or organic phosphorus) are generally the limiting nutrients. In certain anaerobic systems, the availability of trace metals (e.g., Fe, Ni, Co, Mo, and Zn) can be of concern.
Temperature	Rates of growth and metabolic activity are strongly influenced by temperature. Surface soils are particularly prone to wide fluctuations in temperature. Mesophilic conditions are generally best suited for most applications (with composting being a notable exception).
pH	A pH ranging between 6.5 and 7.5 is generally considered optimal. The pH of most ground-water (8.0–8.5) is not considered inhibitory.
Absence of toxic materials	Many contaminated sites contain a mixture of chemicals, organic and inorganic, which may be inhibitory or toxic to microorganisms. Heavy metals and phenolic compounds are particular concerns.
Adequate contact between microorganisms and substrates	For a contaminant to be available for microbial uptake it must be present in the aqueous phase. Thus, contaminants that exist as nonaqueous phase liquids or are sequestered within a solid phase may not be readily metabolized.
Time	This is an important factor in the start-up of bioremediation systems. Even when the first eight considerations in this table are met, lag phases are often observed prior to the onset of activity. In some cases, the dramatic bacterial population shifts that are required for bioremediation will lengthen periods of slow activity.

III. ENHANCEMENT OF CONTAMINANT METABOLISM

The method by which the rate or extent of contaminant metabolism can be increased in a bioremediation system is governed largely by the substrate-specific metabolic processes that result in its transformation. An understanding of contaminant metabolism is essential. In the following sections, an overview of specific metabolic pathways for common contaminant classes is presented.

A. Monoaromatic hydrocarbons

As constituents of gasoline, diesel, and jet fuels, monoaromatic hydrocarbons enter the subsurface environment due to accidental spills and leaking underground storage tanks (UST). These contaminants are commonly found in the environment in the form of free product entrapped or sorbed to porous media or dissolved in water. Monoaromatics are typically referred to as light nonaqueous phase liquids because their specific gravity is less than that of water. Of particular interest in this class of pollutants are benzene, toluene, ethylbenzene, and xylene isomers (BTEX). The biodegradation of these compounds has been and continues to be studied extensively. Under aerobic (containing oxygen) conditions, all the constituents are rapidly biodegraded as primary substrates. Oxygen is important in this process in two ways. First, it is a substrate in the initial attack of the aromatic ring catalyzed by oxygenase enzymes. Second, oxygen serves as the terminal electron acceptor for respiratory chains. Figure 16. 1 illustrates the dual functionality of oxygen in the metabolism of benzene.

The biodegradation of BTEX compounds is not as well characterized under anaerobic conditions as it is under aerobic conditions. Certainly, the biodegradation of all BTEX compounds has been observed under a range of anaerobic electron acceptor conditions, but it does not occur in all cases. In particular, benzene can be recalcitrant under anaerobic conditions. In some cases, however, the metabolism of benzene has been observed in the absence of oxygen. Little is known about the pathways of these processes or the enzymes that may be involved in these reactions.

In any case, the anaerobic degradation of BTEX compounds is generally slower than aerobic processes. Thus, bioremediation systems targeted for BTEX remediation are typically operated under aerobic conditions. The basis of most BTEX bioremediation systems is the enhancement of the rate of aerobic metabolism by increasing the availability of oxygen in contaminated areas. Several methods for doing so are presented later.

B. Polynuclear aromatic hydrocarbons

Polynuclear aromatic hydrocarbons (PAHs) typically result from activities including combustion of fossil fuels and coal gasification processes, and they may also be found in creosote wastes used in wood preservation. PAHs are generally found sorbed to soils and sediments in the natural environment. This class of chemicals contains many compounds with varying biodegradation and physicochemical characteristics. In general, PAH biodegradation is limited to aerobic metabolism and is initiated by oxygenase attack (similar to that depicted in Fig. 16.1). PAHs of three or fewer rings, including naphthalene, fluorene, and phenanthrene, are known to be primary substrates for bacterial growth. Larger PAHs (i.e., four rings and larger) tend to behave as secondary substrates in the presence of the smaller, more water-soluble PAHs.

C. Phenolic compounds

Phenol and chlorinated phenols have historically been used in the treatment or preservation of wood products and have served as bacterial disinfectants. These compounds are biodegraded as primary substrates under aerobic and anaerobic conditions. These compounds are often recalcitrant in the environment due to their toxicity and the low water solubility of certain chlorinated forms (e.g., pentachlorophenol). When present at concentrations lower than toxic thresholds, phenols can be rapidly mineralized by a wide range of microorganisms. As the degree of chlorine substituents increases, the rate of degradation often decreases, especially under aerobic conditions.

D. Chlorinated hydrocarbons

Chlorinated methanes, ethanes, and ethenes comprise a group of compounds commonly referred to as chlorinated hydrocarbons (also referred to as chlorinated solvents). These compounds have been used extensively as degreasers, dry cleaning agents, and paint removers, and they are widely present and persistent in the environment. They are common contaminants of subsurface soils and groundwater, and contamination has resulted from leaking storage facilities or improper disposal practices. Due to their high specific gravity and density, chlorinated hydrocarbon compounds may often be referred to as dense nonaqueous phase liquids (DNAPLs). DNAPLs will typically be found near the lower confining unit of an aquifer since their densities are greater than the density of water. Common chlorinated hydrocarbon contaminant compounds include trichloroethane, perchloroethene (PCE),

FIGURE 16.1 The metabolic pathways of benzene biodegradation under aerobic conditions.

TABLE 16.2 Summary of the biotransformation processes of chlorinated hydrocarbons

Compound	1° Substrate	2° Substrate	Cometabolic substrate	Terminal electron acceptor
Dichloromethane	Yes	Yes	Yes	No
Chloroform	No	No	Yes	No
Carbon tetrachloride	No	No	Yes	No
Perchloroethene	No	No	Yes	Yes
Trichloroethene	No	No	Yes	Yes
Dichloroethenes ^a	No ^b	No	Yes	Yes ^c

^aThree isomers of dichloroethenes exist: 1,1-dichloroethene, *cis*-dichloroethene, and *trans*-dichloroethene.

^bRecent studies have identified oxidative pathways for *cis*-dichloroethene that may yield energy for growth.

^cVinyl chloride and *cis*-dichloroethene are intermediates during the respiration of perchloroethene and trichloroethene to ethene.

trichloroethene (TCE), dichloroethene (DCE), carbon tetrachloride, chloroform, and vinyl chloride.

The metabolism of chlorinated hydrocarbons is perhaps more diverse than that of any other group of environmental contaminants. Depending on the compound of interest, the electron acceptor condition, and the presence of inducing substrates, the metabolism of chlorinated hydrocarbons may occur through primary metabolism, secondary metabolism, cometabolism, or terminal electron acceptor processes.

Table 16.2 lists common chlorinated hydrocarbon contaminants and the processes by which individual compounds are known to be transformed.

E. Nitroaromatic compounds

Nitroaromatics are common pollutants of water and soils as a result of their use in plastics, dyes, and explosives. Typical nitroaromatic contaminants used in explosives manufacture include trinitrotoluene

(TNT), hexahydro-1,3,5-trinitro-1,3,5-triazine (RDX), and octahydro-1,3,5,7-tetranitro-1,3,5,7-tetrazonine (HMX) (Spain, 1995). The nitro group has a strong electron withdrawing functionality, which previously was thought to reduce the potential for oxygenase attack toward the aromatic ring. Recent studies have demonstrated that certain organisms are capable of oxidizing selected nitroaromatic compounds to obtain energy for growth (i.e., primary metabolism). The activity is generally limited to nitroaromatics containing two or fewer nitro groups.

Under anaerobic conditions, nitroaromatic transformation generally yields reduced aromatic products. For example, the product of the complete reduction of nitrobenzene is aniline (aminobenzene). The formation of an aryl amine from an aryl nitro group requires that two intermediate forms be produced; the first is any aryl nitroso intermediate followed by the second intermediate, an aryl hydroxylamine. Recent work has demonstrated the importance of the aryl hydroxylamine intermediate in the ultimate fate of nitroaromatics under anaerobic conditions. The hydroxylamine can be reduced to the amine or undergo more complex reactions that can result in binding with natural organic matter or the formation of an aminophenol through rearrangement reactions.

IV. APPLICATION OF CONTAMINANT METABOLISM IN ENGINEERED SYSTEMS

The process of transforming an individual contaminant molecule into a nontoxic form occurs at the enzymatic level. Potential remediation sites contain kilograms to tons of contaminants distributed over large areas. Reconciling the difference in scale between molecular processes and the cleanup of tremendous volumes of contaminated media is a significant engineering challenge. Fundamentally, the application of microscale phenomena to the field-scale bioremediation of large, complex contaminated sites begins with a thorough analysis of site conditions. Key steps in site characterization may include (i) determination of the contaminants present and their concentration and distribution, (ii) delineation of the volume of material undergoing treatment, (iii) evaluation of the physical and chemical state of contaminants, (iv) analysis of the redox conditions at the site, and (v) establishment of site hydrogeologic conditions. Upon completion of this phase of the investigation, an analysis would be conducted to determine whether *in situ* or *ex situ* treatment or some other technology would be most appropriate given the site conditions. Regardless of the selected

mode of treatment, systems would be designed to create the appropriate ecological conditions to select for organisms that possess the ability to degrade target contaminants. Furthermore, considerations outlined in Table 16.1 would be evaluated to identify potential limiting factors to bioremediation so that modifications or additions to the treatment scheme could be made to enhance the rates of contaminant biodegradation and biotransformation.

Specific bioremediation technologies are discussed in detail later. In all cases, these technologies are predicated on the stimulation of specific metabolic activities. The selection of a bioremediation process begins with the understanding of how specific contaminants may be metabolized. In some cases, metabolism may already be occurring, and application of a bioremediation system to those sites would focus on accelerating the rate of the naturally occurring processes. In other cases, contaminant metabolism may be negligible and conditions may require significant alteration through an engineered process. In all cases, bioremediation technologies intended to distribute metabolic activity throughout a region of contamination that is vastly larger than that of a bacterial cell. Thus, the coupling of microscale metabolic processes with macroscale mass transfer processes is one of the most significant challenges in the development of efficient bioremediation technologies. It should be noted that more detailed information on these technologies may be found in many texts as well as in various collections of monographs. Some of the more pertinent references include *In Situ Bioremediation: When Does It Work?* (Rittman *et al.*, 1993), *Handbook of Bioremediation* (Norris *et al.*, 1994), *Bioremediation: Field Experience* (Flathman *et al.*, 1994), *Innovative Site Remediation Technology: Bioremediation* (Ward *et al.*, 1995), *Bioremediation Engineering: Design and Application* (Cookson, 1995), *Innovations in Ground Water and Soil Cleanup* (Rao *et al.*, 1997), *Soil Bioventing: Principles and Practice* (Leeson and Hinchee, 1997), *Subsurface Restoration* (Ward *et al.*, 1997), and *Innovative Site Remediation Technology Design & Application: Bioremediation* (Dupont *et al.*, 1998).

V. NATURAL BIOATTENUATION

A. Overview

Natural bioattenuation, sometimes termed intrinsic bioremediation or natural bioremediation, refers to the biodegradation or biotransformation of both subsurface soil and groundwater contaminants through

TABLE 16.3 Application of bioremediation treatment options to various classes of contaminants^a

^b?, Undetermined or in developmental stages.

microbially mediated processes. This mechanism for contaminant mass reduction represents a key component of the broader remediation process of natural attenuation which focuses on the reduction of contaminant concentration, mass, mobility, and/or toxicity through natural processes, including dilution, dispersion, volatilization, adsorption to solid surfaces, and chemical and biological transformation reactions. Bioattenuation is a nonintrusive process (i.e., does not require a mechanical or engineered system for remediation) and is generally more cost-effective than other *in situ* and *ex situ* cleanup strategies. This remediation process has been successfully demonstrated in the mitigation of BTEX contamination resulting from leaking underground storage tanks and may also be applicable to the remediation of other compounds, including chlorinated solvents. The applicability of this treatment scheme has not been determined for PAHs, PCBs, explosives, and pesticides (as shown in Table 16.3; Rao *et al.*, 1997). For many UST sites (47%), natural attenuation is the chief mechanism for groundwater remediation, whereas nearly 67% of U.S. states recognize and implement natural attenuation as a viable alternative for soil and groundwater cleanup (USEPA, 1997). Table 16.4 compares the use of natural attenuation with other remediation technologies (some of which are described later) for both soil and groundwater cleanup. It is important to recognize that natural bioattenuation may not necessarily replace active remediation processes, but it does offer an attractive option to complement techniques that may be very costly to implement. For example, at UST sites, large pools of nonaqueous phase liquids may serve as a continual source for groundwater contamination. Typically, a more intensive strategy is required to remove most of the free-phase contaminant before natural bioattenuation is implemented as a cleanup method. Natural bioremediation should also not be

characterized as a "no action" approach to cleanup; rather, it requires both long-term monitoring of the parent contaminant compound and secondary metabolites and monitoring of other chemical and biological markers that are indicative of the attenuation process (Ward *et al.*, 1997). However, the efficacy of natural attenuation for meeting remedial objectives and managing risk of groundwater contamination is controversial in research and regulatory communities. Its role in soil and groundwater cleanup continues to develop as we learn more about quantifying the processes involved.

The rate and extent of contaminant biodegradation are governed by many environmental factors, including contaminant and cell biomass concentrations, temperature, pH, supply of nutrients, adequacy of carbon and energy sources, the presence of toxins such as heavy

metals, availability of contaminants to microorganisms (i.e., contact, contaminant solubility and hydrophobicity, and desorption from solids), time for acclimation, and availability of electron acceptors (Table 16.1). The supply and availability of electron acceptors is often cited as the controlling or limiting factor in the bioattenuation process. Aerobic biodegradation occurs in the presence of oxygen, whereas alternate electron acceptors, including nitrate, sulfate, trivalent iron (Fe^{3+}), and carbon dioxide, are utilized under anaerobic conditions. For relatively soluble petroleum hydrocarbons such as BTEX, the rate and extent of biological transformation of contaminants is typically much greater under aerobic conditions than under oxygen-limited conditions. For highly chlorinated solvents (e.g., PCE and TCE), the rate and extent of biological transformation, through reductive dechlorination, is greater under anaerobic conditions than under aerobic conditions, whereas less halogenated compounds (e.g., vinyl chloride) may be more amenable to aerobic biodegradation.

The oxygen demand exerted by the microorganisms during petroleum hydrocarbon biodegradation generally exceeds the rate of oxygen replenishment, especially in areas of high contaminant concentration (i.e., near the source zone). In fact, the limiting dissolved oxygen concentration for aerobic biodegradation is approximately 2 mg/liter (Rao *et al.*, 1997), although a study by J. Salanitro and coworkers published in *Ground Water Monitoring and Review* in 1997 suggests that this concentration may be as low as 0.2 mg/liter. The characteristic shape of a groundwater

contaminant plume may be partially explained by the presence or absence of oxygen as a terminal electron acceptor. Zones of aerobic biodegradation generally occur on the outermost and leading edges of the plume where contaminated groundwater meets with uncontaminated, well-oxygenated groundwater. Mixing of the two waters via dispersion provides an adequate supply of oxygen for the aerobic biodegradation process. However, contaminant biodegradation in the central region of the plume is generally governed by contaminant-specific anaerobic processes due to the rapid depletion of oxygen in these areas of high metabolic activity. The diffusion rate of oxygen in water is four orders of magnitude less than the diffusion rate in air; thus, the rate of oxygen consumption easily exceeds its rate of transport in water, which results in anaerobic conditions (Norris *et al.*, 1994; Rao *et al.*, 1997). Figure 16.2 presents a typical UST spill and indicates the areas or zones of aerobic and anaerobic biodegradation.

The previous discussion illustrates the importance of oxygen as a driving force in the natural aerobic bioattenuation of subsurface contaminants. Oxygen may be naturally delivered to the contaminant plume either through mixing with uncontaminated groundwater or through reaeration from the overlying unsaturated zone. Reaeration may serve as a significant source of oxygen and is governed by many factors, including soil hydrogeologic properties, soil moisture, precipitation, and respiration rate of soil microorganisms. Macroporous sand materials can easily

FIGURE 16.2 The role of oxygen flux in the bioattenuation of hydrocarbon contaminants (adapted in part from Norris *et al.*, 1994).

and rapidly contribute to the oxygen supply of a contaminant plume, whereas the diffusion of oxygen through clay materials is generally impeded, especially in the presence of moisture. Moisture may cause swelling of certain clay soils and reduces the number of air-filled pore spaces in the soil through which oxygen may easily diffuse. The respiration rate of soils may also serve as a significant oxygen sink and will restrict delivery of the gas to a contaminant plume.

B. Demonstration

Several demonstrations have been completed to determine the efficacy of natural bioattenuation of contaminants in groundwater. A study by C. Y. Chiang and coworkers, published in *Ground Water* in 1989, investigated the aerobic bioattenuation of a petroleum hydrocarbon plume at a gas manufacturing plant in Michigan using a large network of monitoring wells. The contaminated aquifer was located 10–25 ft below the surface and was overlain by coarse sand. The initial mass of benzene at the site was approximately 10 kg; after a period of 21 months, the mass had been reduced to approximately 1.3 kg of benzene. A first-order bioattenuation rate of 0.0095/day was determined for the site. Analysis of groundwater samples throughout the study period revealed an inverse relationship between dissolved oxygen and benzene concentration in the plume. Samples from locations in which the BTX concentration was high were coupled with low dissolved oxygen concentrations as a result of increased microbial activity or biodegradation. Likewise, samples with low BTX concentrations contained higher dissolved oxygen concentrations due to the reduction in oxygen demand. Other natural attenuation processes were found to have very little effect on the reduction of benzene contaminant mass. Only 5% of benzene contaminant loss was attributed to volatilization from the groundwater, and sorption was thought to have little impact on the attenuation process based on the low organic carbon content of the aquifer material. Subsequent modeling and microcosm studies confirmed that natural aerobic bioattenuation was a dominant mechanism in the reduction of contaminant mass at this particular site.

Bioattenuation of chlorinated solvents has also been demonstrated in field studies. In 1995, L. Semprini and coworkers investigated the biotransformation of chlorinated solvents in groundwater at a site in Michigan. A series of multilevel samplers bounding the width and length of the contaminant plume were used to determine the concentrations of TCE, isomers of DCE, vinyl chloride, and ethane with depth in the sandy aquifer. The results of the study

indicated that the reductive dechlorination of TCE had occurred over time in the plume based on the presence of less chlorinated compounds as well as the presence or absence of biochemical markers, including methane (methanogenesis) and sulfate (sulfate reduction).

The transformation of TCE to isomers of DCE (predominantly *cis*-DCE) was associated with sulfate reducing conditions, whereas further transformation of *cis*-DCE to vinyl chloride and ethene was coupled with areas high in methanogenic activity. Although the mass of original TCE contaminant could not be established, Semprini and coworkers suggested that, on the basis of calculated flux rates for each of the contaminant compounds, TCE reduction to ethane was on the order of 20%.

VI. ENHANCED IN SITU BIOREMEDIATION/ BIOATTENUATION

Many *in situ* bioremediation processes have been designed or engineered to maintain or accelerate the biodegradation of organic contaminants in soil and groundwater by supplying those materials which may limit the breakdown of the contaminant compound. For example, in petroleum hydrocarbon-contaminated environments which are nutrient limited, nitrogen, phosphorus, and other minerals may be added to the environmental system (either through soil tilling or through injection into groundwater) to stimulate growth of the contaminant-degrading microbial population. In many cases, the natural supply of oxygen is rapidly extinguished in areas of high metabolic activity, and therefore limits the rate and extent of biodegradation. Oxygen replenishment may also be achieved by soil tilling or by the introduction of air, pure oxygen, hydrogen peroxide (H₂O₂), or other oxygen-releasing materials into soil and groundwater systems. Microorganisms that have been previously acclimated to the contaminant of interest may also be mixed into soil or groundwater environments to stimulate the rate of contaminant decomposition. A recent approach to enhancing *in situ* treatment of chlorinated solvents is the introduction of electron donors such as hydrogen, lactic acid, etc. Installation of reactive barrier walls into groundwater aquifers may also improve the bioremediation of a variety of organic contaminants.

A. Biostimulation

1. Overview

The earliest system of enhanced or engineered *in situ* bioremediation of groundwater was designed

by R. L. Raymond and co-workers with Sun Research and Development Company in Philadelphia and described in a 1978 American Petroleum Institute report titled "Field Application of Subsurface Biodegradation of Gasoline in a Sand Formation." The "Raymond process" was a patented system [U.S. Patent No. 3,846,290 (1974)] in which biodegradation of petroleum hydrocarbons (namely, gasoline constituents) in groundwater by indigenous subsurface microorganisms was stimulated through the injection of nutrients and oxygen. Although subsurface microorganisms require many minerals, the two most common nutrient amendments are nitrogen (as ammonium or nitrate) and phosphorus (as phosphate). The necessary mass of each nutrient may be determined stoichiometrically, and the ratio between carbon, nitrogen, and phosphorus is typically 100:10:1 (C:N:P) (Norris *et al.*, 1994). Many compounds have been used to increase the dissolved oxygen concentration of contaminated groundwater aquifers. Initial attempts to increase dissolved oxygen concentration in groundwater aquifers relied on air sparging of water before injection into the subsurface or sparging air into wells; however, the low solubility of oxygen in water (8–12 mg/liter) precluded maximum contaminant biodegradation. Subsequent methods for oxygen delivery resulted in greater solubility of the gas. Dissolved oxygen concentrations increase to approximately 40–50 mg/liter when sparging with pure oxygen, whereas injection of H₂O₂ can easily result in dissolved oxygen concentrations in the range of 250–500 mg/liter and higher, although H₂O₂ may be toxic to the microorganisms at higher concentrations (Rao *et al.*, 1997).

Oxygen-releasing compounds (e.g., ORC[®], marketed by Regenesis, Inc.) are a more recent innovation for meeting the oxygen demand of microorganisms in subsurface environments. These formulations promote the slow release of oxygen which is produced when magnesium peroxide (the typical active ingredient in these compounds) reacts with water. Oxygen-releasing compounds may be added as a slurry injection or may be placed in a series of wells in the aquifer to form a barrier through which the contaminated groundwater flows. Oxygen is therefore introduced into the central regions of the plume (usually anaerobic) to promote aerobic biodegradation of the contaminant compound (DuPont *et al.*, 1998).

Bioaugmentation, or the introduction of contaminant-acclimated or genetically engineered microorganisms, is another method for enhancing biodegradation of contaminants. Although bioaugmentation has been successfully implemented in a variety of laboratory-scale and larger *ex situ* reactor systems, the success of bioaugmentation in soils and groundwater is limited

(Alexander, 1994). Some of the problems associated with adding an inoculum to soils or groundwater aquifers are the presence of environmental toxins and bacterial predators, adequate conditions for growth (i.e., nutrients, pH, temperature, etc.; see Table 16.1), contact with target contaminant, and cell movement or distribution (Alexander, 1994). The movement or distribution of the inoculum throughout the contaminated region of interest may be inhibited by sorption to solid surfaces, bacterial mobility, and the structure of the porous media. Microorganisms may be able to move freely through large macropores in the soil; however, their movement may be restricted through soil micropores in which larger pools of the contaminant may often reside (Alexander, 1994).

A schematic of a typical biostimulation *in situ* remediation system is presented in Figure 16.3. Groundwater is initially drawn from a series of recovery wells downgradient from the source of contamination. The groundwater is then pumped to an aboveground treatment facility at which both nutrient amendments and oxygen (through either sparging or H₂O₂ injection) are added after the water is initially passed through a contaminant treatment scheme. After addition of chemicals, the groundwater is returned to the aquifer either through an injection well or through an infiltration gallery above the zone of contamination. This process continues until the contaminant concentration is reduced to the target level (DuPont *et al.*, 1998).

2. Demonstration

J. T. Wilson, J. M. Armstrong, and H. S. Rifai reported the bioremediation of an aviation gasoline spill at a Coast Guard air station in Traverse City, Michigan,

FIGURE 16.3 Simplified schematic of an *in situ* biostimulation remediation system (Raymond process).

using nutrient and H_2O_2 amendments (Flathman *et al.*, 1994). The shallow sandy aquifer underlying the site was contaminated by approximately 25,000 gallons of aviation fuel emanating from an UST. Analysis of soil cores taken from the site identified a vertical zone of petroleum hydrocarbon contamination, and the remediation process was aimed at reducing the concentration of BTEX dissolved in the groundwater and bound in the aquifer material. A series of six monitoring wells were placed downgradient of the infiltration wells to quantify BTEX loss due to biodegradation.

Nutrients introduced into the contaminated region included ammonium chloride, disodium phosphate, and potassium phosphate, whereas H_2O_2 was incrementally injected into the subsurface to allow for microbial acclimation (to a maximum of approximately 400 mg/liter oxygen). A high degree of BTEX removal was observed in each of the six monitoring wells. For example, BTEX was reduced from 1200 to 380 mg/liter at a monitoring well 83 ft from the infiltration wells. Benzene was most amenable to biodegradation in the groundwater, whereas the isomers of xylene were most resistant to biodegradation. Remediation of the aquifer material was also investigated by taking soil cores after completion of the experiment. The results indicated that the process generally led to a reduction in BTEX concentrations in the aquifer materials; however, concentrations of total petroleum hydrocarbons at each of the monitoring points remained fairly high. In areas in which oxygen concentration was low, nitrate was determined to be the terminal electron acceptor supporting most of the BTEX biodegradation.

B. Electron donor delivery

1. Overview

The delivery of electron donors to groundwater systems is another *in situ* biostimulation approach to promote or accelerate the biotransformation of chlorinated solvent compounds. Unlike many of the petroleum hydrocarbon contaminants that may be directly utilized by microorganisms to obtain cell energy and promote cell growth, chlorinated solvents are not often used as primary substrates. However, chlorinated solvents may be biodegraded or biotransformed under either aerobic or anaerobic conditions. Under aerobic conditions, biodegradation can be achieved through cometabolic processes in which enzymes capable of breaking down the target contaminant are fortuitously expressed during the biodegradation of other primary substrates. More frequently, chlorinated compounds are biotransformed to less chlorinated products under anaerobic conditions through the process of reductive

dechlorination. Microorganisms require a sufficient supply of electron donors in order to carry out the reductive dechlorination process. A variety of potential electron donors have been evaluated both in field and in laboratory studies and include acetate, methane, hydrogen, ammonia, benzoate, lactate, and methanol. Cocontaminants such as petroleum hydrocarbons may also serve as electron donors in subsurface environments.

Many of the same difficulties experienced with the introduction of nutrients, microorganisms, and other materials into subsurface environments also occur with electron donor delivery (Norris *et al.*, 1994). Excessive microbial growth may result near the point of injection due to the high electron donor concentration and availability. This problem may be further exacerbated by the simultaneous introduction of other materials that are essential for bacterial growth (i.e., oxygen and nutrients).

2. Demonstration

In 1997, in a paper titled "Scale-up Issues for *in situ* Anaerobic Tetrachloroethene Bioremediation" M. D. Lee and co-workers reported laboratory and field experiments relating to electron donor selection and delivery to enhance anaerobic PCE biotransformation. Microcosm studies were used to determine the most efficient substrates to effect PCE dechlorination. The substrates included yeast extract [38% carbon (C)], wastewater (4.5% C), cheese whey permeate (26% C), molasses (29% C), corn steep liquor (17% C), manure tea (3% C), sodium benzoate (58% C), and acetate (29% C). The field site under investigation was a landfill associated with a chemical plant in Texas. The saturated zone of the aquifer underlying this site consisted primarily of sand. A series of injection, withdrawal, and monitoring wells were used in the field experiments which were designed to determine an optimal electron donor delivery system.

The initial microcosm study investigated dechlorination of chlorinated ethenes (23 μM PCE, 0.6 μM TCE, and 3.3 μM 1,2-DCE) using yeast extract, wastewater, molasses, corn steep liquor, and manure tea at varying initial carbon loadings. A high degree of carbon utilization was achieved in each microcosm (>60% TOC removal), and PCE was transformed to vinyl chloride at carbon concentrations >60 mg/liter. Cell counting experiments indicated a positive relationship between the amount of carbon in the microcosm and the number of microorganisms present. A second microcosm experiment, using sodium benzoate, sodium acetate, corn steep liquor, and molasses, studied the effect of very high organic loadings on both PCE

dechlorination and microorganism concentration. In contrast to the results from the first study, higher organic loadings inhibited TOC removal and resulted in either no transformation or only partial transformation of PCE.

The field tracer experiments compared the injection and distribution of the substrate and nutrient amendments under three conditions: tracer (bromide) injection at the rate of groundwater flux, tracer (iodide) injection at a rate of 60 times groundwater flux, and cross-gradient injection [bromide, substrate, and nutrients (N, P)] at a rate of 3.8 liters/min for the withdrawal wells (two) and the injection well. Distribution or dispersion was enhanced when the injection rate was increased to 60 times the natural groundwater gradient. The third condition, employing the cross-gradient injection scheme, further increased dispersion of the bromide tracer. Measurements of TOC also indicated that sodium benzoate was successfully transported downgradient from the injection well. However, transport of both the injected nutrients and electron acceptor (sulfate) was retarded either by sorption to the aquifer solids or by biodegradation processes.

C. Bioventing

1. Overview

Bioventing is another *in situ* technique designed to stimulate aerobic biodegradation of contaminants by replenishing oxygen levels in oxygen-depleted, unsaturated zone environments. The process was first described by J. T. Wilson and C. H. Ward in an article published in 1986 in the *Journal of Industrial Microbiology*. R. E. Hinchee, R. R. DuPont, R. N. Miller, and others were responsible for developing and testing the process (Leeson and Hinchee, 1997). Bioventing has been successfully applied at several petroleum hydrocarbon-contaminated sites and may also be implemented to remediate sites contaminated with chlorinated solvents, although it typically requires the addition of substrates to promote cometabolism of the chlorinated hydrocarbons (Norris *et al.*, 1994). A recent report suggests that bioventing is being used at less than 1% of UST contaminated soil sites. However, this percentage translates into the application of bioventing at more than 800 UST sites (USEPA, 1997). Bioventing is designed to emphasize biodegradation over contaminant volatilization; however, the relationship between the two mechanisms may be determined by both the properties of the contaminant of interest (e.g., molecular weight and vapor pressure) and site conditions (Norris *et al.*, 1994;

Leeson and Hinchee, 1997). Hydrocarbon contaminants with higher vapor pressures will tend to volatilize with injection of air and may not be suitable for bioventing, whereas biodegradation of heavy hydrocarbons with lower vapor pressures may be achieved using this treatment technology (Cookson, 1995).

In addition to contaminant characteristics, soil properties play a major role in the success of bioventing applications. These properties include physical characteristics, such as hydraulic conductivity, gas permeability, and moisture content, as well as properties that will affect the growth of microorganisms (in addition to oxygen supply), such as temperature, pH, and nutrient supply. Bioventing applications are best suited for soils with high gas permeabilities so that the injected air readily moves through the contaminated soil matrix (Leeson and Hinchee, 1997; Ward *et al.*, 1997). The flow of air may be severely restricted in low-permeability soils and will subsequently impact the extent of contaminant biodegradation. Gravel and sand may be considered highly gaspermeable materials, whereas silts and clays represent soils with lower gas permeabilities. Although moisture is required by soil microbes for contaminant metabolism, high percentages of water in the soil will negatively impact the flow of oxygen in the soil pores. The majority of pore spaces in high moisture content soils are filled with water, and the diffusion of oxygen through water is much slower than through air.

As with other treatment technologies, microbial growth factors (temperature, pH, and nutrients) may also impact the rate and extent of biodegradation in bioventing applications. Higher temperatures are generally associated with higher rates of contaminant biodegradation. However, Leeson and Hinchee (1997) pointed out that psychrophilic microorganisms at a field test site in Alaska were able to significantly biodegrade petroleum hydrocarbons in the subsurface. Nutrient amendment also may need to be considered in deficient subsurface soils. Delivery or transport of nutrients to the target zone may be difficult and will also depend on the soil physical properties. Soils generally contain sufficient nutrients to support the biodegradation of hydrocarbon contaminants, and the advantage of adding nutrients to subsurface soils has not been firmly established (Leeson and Hinchee, 1997).

Figure 16.4 presents a schematic of a bioventing system (Leeson and Hinchee, 1997). Bioventing is accomplished by advective flow of air through a series of vent wells into areas that have exhausted their supply of oxygen in the soil gas. Monitoring points are distributed throughout the zone of contamination to determine both the decrease in oxygen concentration

FIGURE 16.4 Schematic of a bioventing system (adapted from Leeson and Hinchee, 1997).

and the increase in the carbon dioxide concentration (primary product of biodegradation). Low airflow rates are usually incorporated into the system design to favor contaminant biodegradation over volatilization. In theory, contaminant biodegradation should be much greater than volatilization; therefore, management of gases that are transported to the soil surface is usually not required. If volatilization is high, a separate extraction and treatment system will have to be installed to handle the vapors being generated by the bioventing system. Bioventing is frequently applied in cooperation with and usually following soil vapor extraction (SVE) for vadose zone remediation.

2. Demonstration

One of the earliest and best known bioventing remediation systems was implemented at a site at Hill Air Force Base in Utah where 27,000 gallons of jet fuel were spilled (Leeson and Hinchee, 1997). Fuel contamination migrated to a depth of approximately 65 ft in the unsaturated zone, which consisted primarily of sand and gravel constituents. The average contaminant concentration in the soils was approximately 400 mg/kg. A series of vent wells were installed over the length of the contamination to evaluate the potential of bioventing. Enhanced bioventing using both moisture and nutrient addition was also investigated. The system was initially constructed to investigate contaminant volatilization and capture at higher air flow rates (SVE); however, after several months of testing,

lower airflow rates were employed to favor biodegradation over volatilization.

A series of soil samples were taken with depth before and after implementation of the SVE and bioventing remediation system at the site. After application of SVE and bioventing, nearly all of the post-treatment hydrocarbon concentrations in the soils were < 5 mg/kg, indicating successful cleanup of the site. It was estimated that approximately 1500 lbs of hydrocarbon fuel was removed through volatilization, whereas 93,000 lbs of fuel was removed through biodegradation. Much of the biodegradation of the fuel was attributed to the bioventing phase of cleanup. Enhanced bioventing by adding moisture and nutrients yielded mixed results. The addition of moisture resulted in a significant increase in contaminant biodegradation, whereas addition of nutrients (N and P) did not enhance removal of the petroleum hydrocarbons.

D. Permeable reactive barriers

1. Overview

The use of *in situ* permeable reactive barriers is another method that introduces reactants which may stimulate the biotic or abiotic transformation of environmental contaminants. As opposed to other *in situ* remediation methods that rely on injection of reactants (i.e., oxygen and nutrients) and their transport with groundwater flow through the contaminated aquifer, stationary barrier walls containing the reactive porous media are

placed into the subsurface using a variety of methods. The contaminated groundwater is directed to and passes through the reactive barrier, thus enabling reaction between the porous media and the contaminant of interest. Permeable reactive barriers are typically used to treat target contaminants, including petroleum hydrocarbons and chlorinated solvents (Table 16.3).

A schematic of an *in situ* permeable reactive barrier is presented in Figure 16.5. The barrier may span the width of the zone of contamination or a series of sheet piling may be inserted into the subsurface which direct the contaminated water through the reactive barrier. This “funnel and gate” system was devised R. C. Starr, J. A. Cherry, and other researchers at the University of Waterloo and published in 1994 in *Ground Water*. In cases in which the reactants in the barrier may be rapidly extinguished due to biochemical reactions, these materials may be replenished by designing replacement cassettes that may be easily exchanged in the barrier. Cassettes can also be placed in series to target the biodegradation or biotransformation of a particular contaminant or to remediate groundwater with many contaminants, each of which has specific requirements for degradation. Permeable reactive barrier technologies may also incorporate a series of smaller reactive walls if the size of the plume is large, thus facilitating easier removal and replacement when compared to a single large wall.

Starr, Cherry, and others pointed out that the most important considerations for the design and application

of this type of system include (i) time required to effect desired biochemical reaction (combination of groundwater flow rate, reaction rate, influent contaminant concentration, and target effluent contaminant concentration), (ii) the potential formation of hazardous products resulting from reactions within the reactive barrier, and (iii) costs associated with installation and media regeneration. Examples of reactants or amendments used in permeable reactive barrier technologies to enhance contaminant biodegradation and transformation include nutrient amendments (N and P), oxygen addition using oxygen-releasing compounds or biosparging (introduction of air), and introduction of zero valent iron to achieve abiotic reduction of chlorinated compounds.

2. Demonstration

J. F. Barker, J. F. Devlin, and co-workers demonstrated the use of permeable reactive barrier remediation technologies at the Canadian Forces Base Borden site in Ontario, Canada. The work was documented in a 1998 report sponsored by the Department of Defence Advanced Applied Technology Demonstration Facility (AATDF) at Rice University. Contaminants within the groundwater plume targeted for remediation using this *in situ* technology included carbon tetrachloride, PCE, and toluene. Remediation of the highly chlorinated aliphatics (i.e., carbon tetrachloride and PCE) was accomplished through both biotic

FIGURE 16.5 Funnel and gate system to remediate contaminated groundwater using permeable reactive barriers (adapted in part from Starr and Cherry, 1994).

and abiotic reduction processes, whereas biodegradation of the less chlorinated aliphatics and toluene was achieved in an aerobic treatment zone. Three test gates containing different sequences of reactive cassette barriers were installed at the site. Gate 1 consisted of two granular iron cassettes (to effect abiotic reductive dechlorination of chlorinated hydrocarbons) followed by a cassette containing oxygen-releasing compounds. Gate 2 did not contain reactive media and served as a control and/or natural attenuation gate. Gate 3 contained a benzoate injection well (to serve as substrate for microorganisms and to achieve anaerobic conditions for microbially mediated reductive dechlorination) followed by a biosparging wall. Initial spiked contaminant concentrations in the groundwater were approximately 1 or 2 mg/liter for carbon tetrachloride and PCE and 10 mg/liter for toluene.

Results from Gate 1 indicated that PCE was completely transformed to ethane and ethene (half-life = 0.5 days). Carbon tetrachloride was transformed to chloroform prior to reaching the gate and was rapidly dechlorinated in the iron barrier to dichloromethane. High pH next to the granular iron cassette required emplacement of the ORC downgradient at lower pH to stimulate oxygen release and toluene biodegradation. Gate 2 (natural biodegradation and biotransformation) results also indicated biotransformation of carbon tetrachloride and chloroform (each having a half-life of approximately 11 days). In Gate 3, PCE was successfully transformed to *cis*-DCE. Subsequent passage of the contaminated groundwater in Gate 3 through the biosparging wall (aerobic zone) resulted in biodegradation of toluene as well as the less chlorinated end products of reductive dechlorination produced in the anaerobic zone (e.g., *cis*-DCE).

VII. ENHANCED EX SITU BIOREMEDIATION

Like *in situ* processes, enhanced *ex situ* bioremediation processes are engineered to accelerate the biodegradation or biotransformation of organic contaminants in soils and solids. In many cases, *ex situ* technologies generally offer better control of the parameters that govern biodegradation than do *in situ* techniques. *Ex situ* bioremediation technologies include land farming, composting, and slurry reactors. Land treatment employs nutrient addition and aeration (by tilling) to stimulate biodegradation of land-applied wastes. Composting of contaminated soils and sludges is a high-temperature, exothermic process in which bulking agents (e.g., wood chips and mulch) and, in some cases, nutrients are added to encourage biodegrada-

tion. Finally, *ex situ* bioslurry reactors may be used to treat either contaminated liquids or solids through nutrient addition, aeration, and bioaugmentation.

A. Land treatment

1. Overview

Land treatment or land farming refers to the accelerated aerobic biodegradation of organic wastes in either near-surface or excavated soils through the addition of nutrients, lime (pH control), and moisture and through increased aeration by tilling or other mechanical mixing (Loehr and Malina, 1986). Biodegradation is generally carried out by indigenous soil microorganisms, although some form of bioaugmentation may enhance the rate of degradation. Typically, land farming is an *ex situ* process whereby the contaminated soils are excavated from a site and sent to an engineered treatment unit (also termed a prepared bed system or reactor); however, *in situ* methods (nutrient addition and tilling) may be adequate to enhance biodegradation of the soil contaminants near the surface of excavated wastes that are mixed or tilled into the top soil layer (to a depth of approximately 1 ft). A wide variety of organic contaminants have been successfully treated in land farming applications, including petroleum hydrocarbons, pesticides, PCPs, PCBs, and PAHs (Cookson, 1995).

Land farming typically requires the addition of nutrient amendments (namely, N and P) to the soils to enhance biodegradation of contaminants. The minerals may be introduced into the soil either as a solid or mixed with water and applied through a spraying system (Cookson, 1995). The spraying system may also provide needed moisture to soils and enhance contaminant biodegradation. Plowing, tilling, or other methods of mechanical mixing of the soils stimulates biodegradation through (i) mixing and distribution of soil amendments (nutrients, lime), (ii) distribution of contaminants (by breaking up soils) and increased contact between contaminants and microorganisms, and (iii) increased aeration of soils (increased oxygen supply) (DuPont *et al.*, 1998; Ward *et al.*, 1995; Cookson, 1995).

Figure 16.6 presents an engineered land treatment system. Much like conventional municipal solid waste treatment units or landfills, controls or collection systems may be placed in the land treatment unit. To prevent groundwater contamination, the base of a typical land treatment unit is covered with a highly impermeable clay or geosynthetic (plastic) liner. A series of leachate recovery pipes are then placed near the base of the system to collect wastes that may percolate through the soil. A thick layer of sand covers the collection system, and the contaminated soil is then placed on the

FIGURE 16.6 Typical land treatment unit (inset depicts liner configuration) [adapted in part from Cookson (1995) and Alexander (1994)].

sand layer. Collected leachate may be recycled or sent to another treatment system. A cover or enclosure may be added to the land treatment unit to eliminate rainfall percolation and off-site migration of contaminant vapors (Cookson, 1995; Alexander, 1994).

2. Demonstration

In 1979, J. T. Dibble and R. Bartha published work (*Soil Science*) on the land treatment of hydrocarbon-contaminated soil resulting from a pipeline leak in New Jersey in which approximately 1.9 million liters of kerosene was spilled onto 1.5 hectares (ha) of an agricultural plot. After removal of approximately 200 m³ of heavily contaminated soil, both lime and nutrients (N, P, and potassium) were applied to the field soil (to a depth of 117 cm) to enhance biodegradation. Aerobic biodegradation of the kerosene contaminant was further stimulated by periodic tilling or mixing of the soil to promote distribution of oxygen. The applied nutrient concentrations were 200 kg nitrogen/ha, 20 kg phosphorus/ha, and 17 kg potassium/ha and were added at two different times after an initial loading of 6350 kg/ha of lime. The contaminated soil was characterized as a well-drained, sandy loam soil. Kerosene biodegradation was monitored during a 24-month period to determine the efficiency of the treatment system.

Over the course of the experiment, kerosene concentrations in the soil decreased from 8700 mg/kg to very

low levels in the upper 30 cm of the soil. Likewise, kerosene concentration in the lower portion of the soil (30- to 45-cm depth) also decreased over the 24-month period to < 3000 mg/kg. Biodegradation was determined to be the primary mechanism for removal (compared to volatilization) based on the disappearance patterns of compounds of varying molecular weight. The rate of biodegradation in the upper portion of the soil was initially greater than the rate of biodegradation in the lower portion. However, more rapid kerosene biodegradation was observed in the lower portion of the soil after 6 months of system operation and evaluation. Temperature also played a major role in the biodegradation of the kerosene contaminants. The greatest decreases in kerosene concentration due to biodegradation occurred during time periods when temperatures were at or higher than 20 °C; contaminant removal was diminished at lower temperatures.

B. Composting

1. Overview

Composting is another *ex situ* process in which organic compounds are biodegraded, biotransformed, or otherwise stabilized by mesophilic and thermophilic bacteria. Addition of other readily biodegradable materials, bulking agents, moisture, and possibly nutrients to contaminated soils enhances or stimulates the composting

process (Ro *et al.*, 1998) Nitroaromatics, petroleum hydrocarbons, PAHs, chlorinated phenols, and pesticides are classes of contaminants that are amendable to biodegradation using a composting system (Table 16.3).

Composting at high temperatures typically accelerates the biodegradation or biotransformation process and has historically been required to kill pathogenic organisms remaining in wastewater treatment sludges; however, high-temperature composting of contaminated soils and other solids may not be required due to the absence of pathogens in these materials (Cookson, 1995). As a result, composting of contaminated soils may occur either under mesophilic (15–45°C) conditions or under thermophilic (50–70°C) conditions. The most suitable temperatures for composting range from 55 to 60°C, whereas temperatures higher than 70°C severely inhibit the ability of the microorganisms to metabolize or transform the contaminants (Ro *et al.*, 1998). Bulking agents are used to increase the pore space or porosity of contaminated soil which results in greater air movement through the compost pile and higher rates of aerobic biodegradation. Typical bulking agents used in composting include wood chips, straw, tree bark, and plant matter (Alexander, 1994). Moisture content may also be a controlling parameter in the composting of contaminated soils. Excess moisture will impede the diffusion of oxygen through the compost pile and therefore restrict aerobic biodegradation. Optimal percentage moisture contents in compost piles range from 50 to 65% (Ro *et al.*, 1998). Cookson (1995) reports that hydrocarbon biodegradation in a composting system is optimized at a moisture content of 60%, whereas slightly lower moisture contents are suitable for other hazardous constituents.

The three most common types of composting systems are the windrow, static pile, and in-vessel systems. In windrow composting systems, the composting materials (mixture of organic material, contaminated soil, and bulking agents) are placed in long rows and are turned or mixed using a mechanical device to provide aeration or oxygen replenishment. Static pile systems are similarly arranged in long rows of composting material, but oxygen is supplied through a series of pipes that are placed at the base of the piles. Finally, in-vessel systems are typically enclosed units in which composting materials are transported on a conveyor system through a reaction vessel that is responsible for mixing, forced aeration, and temperature control (Cookson, 1995). In-vessel systems allow for greater engineering control (i.e., capture of volatile compounds and temperature and aeration regulation) and may greatly accelerate the biodegradation process when compared to the other two types of composting systems.

2. Demonstration

In 1992, R. T. Williams, P. S. Ziegenfuss, and W. E. Sisk published work in the *Journal of Industrial Microbiology* on the static pile composting of explosives contaminated sediments from two U.S. Army facilities—Louisiana Army Ammunition Plant (LAAP) and Badger Army Ammunition Plant (BAAP). Target contaminants to be biodegraded using this remediation scheme included TNT, RDX, HMX, tetryl, and nitrocellulose (NC). Additives to the contaminated soils included alfalfa, straw, manure, wood chips, and horse feed in varying combinations along with nitrogen, phosphorus, potassium, and water. The initial concentration of contaminants in the LAAP soil included 56,800 mg/kg TNT, 17,900 mg/kg RDX, 2390 mg/kg HMX, and 650 mg/kg tetryl, whereas the initial concentration of NC in the BAAP soil was 18,800 mg/kg. Compost pile temperatures of the various configurations (two LAAP piles and four BAAP piles) were set at 35 and 55°C to investigate composting of explosives under both mesophilic and thermophilic conditions.

The results indicated successful remediation of the contaminants using various combinations of bulking agents and temperatures. For the LAAP soil static piles, the combined concentration of explosives decreased from 17,870 to 74 mg/kg in the thermophilic pile, whereas mesophilic conditions effected a concentration decrease from 16,560 to 326 mg/kg during the 153-day test cycle. Half-lives for TNT, RDX, and HMX under thermophilic conditions were 12, 17, and 23 days, respectively. Half-lives of the contaminants under mesophilic conditions were nearly double those calculated under thermophilic conditions. Very low levels of amino transformation products (e.g., 2-amino-4,6-dinitrotoluene, 4-amino-2,6-dinitrotoluene) were detected at the end of the test cycle. Nitrocellulose concentrations were dramatically reduced in the BAAP soil static piles. Under thermophilic conditions, NC concentration in two of the test piles was reduced from an average of approximately 13,090 mg/kg to approximately 20 mg/kg.

R. Valo and M. Silkinoja-Salonen (1986) investigated windrow composting of chlorophenol-contaminated soils from a sawmill in Finland. Two 50-m³ compost piles were constructed and contained contaminated soil along with bark and ash. Nitrogen, phosphorus, and potassium were also added to the compost pile in the aqueous phase to ensure adequate nutrient levels throughout the system. The initial concentration of chlorophenols in the soil ranged from 400 to 500 mg/kg soil, whereas the initial concentration in the compost ranged from 200 to 300 mg/kg. The composting unit was monitored over the course of 17 months with the

majority of sampling and analysis being conducted during the first 5 months of operation (summer months, presumably when microbial activity was greatest).

The results of the study indicated a significant decrease in the concentration of chlorophenols in the composting unit. Most of the contaminant loss or destruction occurred during the first few months of operation. The concentration of chlorophenol decreased rapidly to approximately 30 mg/kg after a few months of operation, and the concentration decreased to approximately 15 mg/kg by the end of the test period. Bacterial identification and counts also indicated that the compost material contained a greater number of pentachlorophenol-degrading microorganisms when compared to an agricultural clay soil that was not previously contaminated by chlorophenols. Subsequent jar tests on the compost material with radiolabeled pentachlorophenol confirmed that biodegradation was a major removal mechanism because approximately 30% of the radiolabeled carbon evolved as $^{14}\text{CO}_2$ during a 40-day test period.

C. Bioslurry processes

1. Overview

Slurry reaction systems are another type of *ex situ* bioremediation process in which biodegradation of contaminants is effected either in a highly controlled bioslurry reactor or in a waste lagoon. Typically, contaminated soils, sediments, or other solids are added to the system and mixed with a host of amendments, including water, nutrients, oxygen (if an aerobic environment is desired), surfactants to enhance contaminant mobilization, and/or microorganisms that may specifically biodegrade or biotransform the contaminant of interest. Bioslurry systems, especially enclosed bioreactors, offer a high degree of engineering control. Most of the major parameters that impact contaminant biodegradation (e.g., temperature, pH, and nutrient addition) may be monitored and adjusted using this remediation approach. Many contaminant compound classes are amenable to biodegradation using bioslurry processes and include phenols, chlorinated phenols, PAHs, pesticides, chlorinated hydrocarbons, and petroleum hydrocarbons (Cookson, 1995; Alexander, 1994). Highly viscous contaminants such as tars and certain oils may not be appropriate for bioslurry treatment.

Treatment of the contaminated material may occur either in a bioslurry reactor or in a lagoon. The bioreactor system may consist of a single reactor or a series of reactors, and these reactors are typically closed to the atmosphere to prevent escape of volatile compounds and to maintain system control. Both the size and the

volume of the bioslurry reactors can be highly variable. The percentage solids concentration in these reactors ranges from 5 to 50% and depends on both the physical properties of the soil and the characteristics of the treatment system. Reactors in series offer a potential method of creating both aerobic and anaerobic environments in sequence, and this type of system may be very efficient in coupling the reductive dechlorination of highly chlorinated solvents (anaerobic conditions) with the subsequent metabolism of less chlorinated compounds (aerobic conditions). Typically, engineered waste lagoons vary in size and may be equipped with a variety of mixers and aerators to provide oxygen to the system. As in land treatment applications, a highly impermeable layer of clay soil or synthetic liner should be situated at the base of waste lagoons to prevent contaminant percolation into groundwater.

The continuously mixed bioreactors or waste lagoons have significant engineering advantages compared to other *ex situ* technologies such as composting and land farming, although bioreactor systems may be costly to operate (Cookson, 1995). The mixing of the solids within the reactor enhances the distribution of both the solid materials containing the contaminants and the amendments that are added to the reactor system. Increased aeration and mass transfer of oxygen throughout the bioreactor as a result of mixing or sparging encourages aerobic biodegradation of the contaminants. If the bioslurry system contains volatile compounds, the rate of volatilization may be increased due to agitation and mixing. Both the accessibility of the contaminant to the microorganisms (contact) and the fraction of bioavailable contaminant are increased in this type of reactor system.

Bioslurry processes promote the breakup of aggregated soil particles that may sequester or contain high concentrations of the target contaminant. This breakup of larger particles into smaller ones leads to a greater soil surface area to volume ratio and thus may increase contaminant desorption by maximizing surface contact with the aqueous phase. Contaminated clay soils may be especially amenable to bioslurry treatment processes due to their decreased permeability and difficulty in treating *in situ*. Organic contaminants adsorb strongly to adhesive clay materials and may be easily entrapped in the intra- and interparticle pore spaces, and subsequent transport of materials (i.e., nutrients, oxygen or other electron acceptor, and microorganisms) through clay soils is very difficult.

2. Demonstration

In 1991, G. C. Compeau and coworkers reported results from laboratory-scale experiments used in the design

and implementation of a full-scale bioslurry reactor treatment system. The full-scale system was designed to treat 3400 cubic yards of PCP-contaminated soil from a spill. PCP concentrations in the soil were variable, with a maximum of 9000 mg/kg. Initial testing of the contaminated soil indicated that the indigenous microflora were not capable of breaking down the PCP contaminant; therefore, subsequent bench and full-scale treatment systems incorporated specialized PCP-degrading microorganisms to augment the existing soil organisms and stimulate biodegradation of the contaminant.

The laboratory-scale bioslurry treatability studies indicated that for a variety of solids with concentrations ranging from 5 to 40%, PCP could be successfully biodegraded when the reactor was inoculated with the PCP-degrading culture. For example, in the 40% solids concentration bioslurry test with an initial concentration of approximately 275 mg/liter, very little of the PCP was removed from the system during the initial 13-day test period. After inoculation, nearly all the PCP in the reactor was biodegraded during a 10-day period. The laboratory studies also revealed that the majority of the PCP contaminant resided within the more coarse particles, which may not be easily suspended in a bioslurry reactor system. As a result, design of the full-scale treatment system was amended to include a washing step to desorb the PCP from the coarse particles. The wash solution containing PCP along with the finer unwashed soil particles represented the major influents to the bioslurry reactors.

A pair of 25,000-gallon bioslurry reactors were used in the full-scale cleanup operation. Nitrogen and phosphorus were added to the reactors to meet microbial growth requirements. Results from the full-scale experiment supported the laboratory findings that inoculation was necessary to stimulate PCP biodegradation. A testing period of 2 weeks was required to decrease PCP soil concentrations from 370 to <0.5 mg/kg in one of the inoculated reactors. This degree of treatment was also reached in the second reactor, but only after addition of the inoculum following a 7-day test period in which biodegradation did not occur. It is generally believed that bioaugmentation decreases the lag time in biodegradation studies but that, given time, selection processes will result in microbial populations capable of degrading target contaminants.

VIII. SUMMARY

Bioremediation refers to the transformation of organic wastes by microorganisms into biomass, carbon dioxide, water, and inorganic salts, depending on the structure of the compounds in the waste. These organic waste

materials may also be biotransformed to less toxic compounds or compounds that may be more amenable to complete mineralization. Many *in situ* and *ex situ* technologies are currently available to address organic waste contamination in both soils and groundwater.

Natural bioattenuation is an *in situ* method for remediating contaminated subsurface soils and groundwater. It is a nonintrusive method that takes advantage of the abilities of natural microflora in subsurface environments to biodegrade organic contaminants. Although natural bioattenuation does not require complex engineered systems, monitoring for contaminant concentration and biochemical markers is necessary to validate the efficiency of this type of treatment option. Enhanced *in situ* bioremediation technologies include the Raymond process (biostimulation), electron donor delivery, bioventing, and permeable reactive barriers. Biostimulation technology involves the addition of nutrients (namely, N and P), oxygen, and perhaps microorganisms to groundwater aquifers to enhance biodegradation of organic contaminants. Oxygen may be added to the groundwater by injection of air, pure oxygen, hydrogen peroxide, or oxygen releasing compounds. Injection of microorganisms into the subsurface, or bioaugmentation, also may be an option for biodegradation enhancement; however, to date there has been little success in field-scale experiments.

In situ biodegradation and biotransformation of chlorinated organic compounds may be accelerated by the injection of electron donors, such as lactate, methanol, and hydrogen, to the contaminant region of interest in groundwater. In a cometabolic process, breakdown of the primary substrate (e.g., methane) leads to the fortuitous expression of enzymes that are capable of oxidizing highly chlorinated organics such as TCE. Biotransformation through reductive dechlorination also requires an adequate supply of electron donors to serve as a primary substrate for the microorganisms that mediate this process.

Bioventing of contaminated subsurface unsaturated zone soils focuses on delivering oxygen to areas in which oxygen has been previously depleted due to microbiological reactions in the soil. This treatment technology is typically applied to soils that have high permeabilities and thus a greater ability to transfer oxygen to the contaminant region. The treatment technology is designed to favor contaminant biodegradation over volatilization, but site hydrogeology and contaminant physical properties may also have an impact on the effectiveness of the two mechanisms. Permeable reactive barriers provide another *in situ* method in which groundwater is routed through a wall or barrier containing materials that will enhance either the biodegradation or biotransformation of

organic contaminants. Materials contained in the reaction zone may include both nutrients and oxygen releasing compounds to enhance aerobic biodegradation of contaminants or other reactive agents such as zero-valent iron that lead to the abiotic reductive dechlorination of chlorinated solvents.

Land treatment or land farming is an *ex situ* method to treat contaminated soils and sludges. Excavated materials are placed either in an engineered treatment unit or on top of the natural soil surface. Biodegradation in these systems is enhanced through tilling and mixing to promote aeration, nutrient amendment, and possibly the addition of contaminant-degrading microorganisms. *Ex situ* composting of contaminated soils is achieved by addition of bulking agents such as wood chips to promote aeration, nutrients, and readily biodegradable materials to the contaminated soils. These mixtures are then placed in windrow, static pile, or in-vessel composting systems in which higher temperature, thermophilic conditions are initiated to accelerate the biodegradation process. Finally, bioslurry processes promote treatment of contaminated soils, solids, and sludges by placement in bioslurry reactors and mixing with water, nutrients, oxygen, microorganisms, or other materials that might enhance the biodegradation or biotransformation of the contaminant. Bioslurry processes offer a high degree of control over the parameters that influence biodegradation, including temperature, pH, and nutrient concentration, but they can be expensive when compared to land treatment and composting.

Bioremediation processes for the treatment of contaminated environmental media such as soils and the saturated (aquifer) and unsaturated (vadose) zones of the subsurface may prove to be the most cost-effective treatment options depending on site-specific remedial objectives. In common with most other remediation technologies, bioremediation processes are usually applied as part of a system or treatment in conjunction with other complementing processes to obtain optimal results.

GLOSSARY

biochemical oxygen demand (BOD) The amount of dissolved oxygen (DO) needed to biologically degrade the organic compounds in an aquatic environment. BOD measurements are conventionally carried out according to the BOD 5-day method which measures the DO by titration (modified Winkler method) before and after a 5-day sample incubation period during which biodegradation occurs.

biological sensing element A biomolecule or a biomaterial used in a biosensor for analyte recognition; sometimes referred to as a biological recognition element. It undergoes a specific biological reaction with the analyte so that the analyte can be selectively detected by the biosensor. Examples include enzymes, antibodies, DNA oligomers, and microorganisms.

flow injection analysis (FIA) A technique sometimes used in flow-type biosensors; developed in the 1970s. The sample is injected directly into carrier solution running through fine tubes of manifolds which include an electrical detection apparatus. Reactions such as those resulting in fluorescence or chemiluminescence occur *in situ* and are detected as electronic signals. FIA systems afford precise control of the mixing ratio of injected samples and carrier solutions, which results in highly reproducible measurements. Because the detection by FIA is simple, rapid, precise, and continuous, it is used for various

measurements, such as in medical diagnosis, food quality control, and environmental monitoring.

glucose oxidase An enzyme which catalyzes glucose oxidation. It is usually suitable for industrial use because of its high stability. It is one of the typical biological sensing elements and was used in the first biosensor.

transducer An electronic signal-transducing element that can convert a change in the concentration of a product of a biological reaction into an electronic signal. Examples are electrodes and optical apparatus.

A Biosensor is broadly defined as a sensing system which uses biological reactions such as enzymatic or immunological reactions. Most biosensors are composed of a biological sensing element and a transducer.

Many biosensors (Cass, 1990; Suzuki, 1990; Buerk, 1993) have been constructed since the first report describing the development of the first enzyme sensor for glucose measurement by Clark in 1962 (Buerk, 1993). This biosensor measured the product of an enzyme reaction using an electrode, which was a remarkable achievement even though the enzyme was not immobilized on the electrode.

Today's basic biosensors originated from the investigation by Updike and Hicks in 1967 (Buerk, 1993). Their sensor combined membrane-immobilized glucose oxidase with an oxygen electrode, and oxygen measurements were carried out before and after the enzyme reaction. Many other biological elements and

transducers have been examined since this first glucose biosensor was developed. For example, in 1977 Karube reported the first microbial sensor which used the whole cell as a biological sensing element. Many immuno-sensors using antibodies were fabricated in 1980s and recently DNA, RNA, and even artificial recognition elements have been employed. Transducers have also been improved, and novel transducing elements such as optical detectors, including surface plasmon resonance (SPR) detectors, are widely used in modern biosensors.

I. PRINCIPLE OF BIOSENSORS

A biosensor is a detection system composed of biological sensing elements, such as enzymes, antibodies, microorganisms, and DNA, and an electronic signal-transducing element (Fig. 17. 1) (Buerk, 1993). A transducer can convert a change in the concentration of a product of a biological reaction into an electronic signal. For example, an oxygen electrode converts a change in the oxygen concentration of a sample caused by enzymes or biodegradation into a change in electric current. The transducers used in biosensors include electrodes, piezo-electric quartz crystals, and optics. Many biosensors can be applied to important fields such as diagnosis and environmental monitoring.

The principle of a simple glucose sensor using glucose oxidase (GOD) is shown in Fig. 17.2. The target analyte, glucose, is a substrate of GOD. Glucose diffuses into the membrane and a biological reaction occurs within the membrane. When GOD catalyzes the glucose oxidation, dissolved oxygen in the sample is consumed and gluconic lactone and hydrogen peroxide are produced. The oxygen electrode detects a change in dissolved oxygen concentration of the

sample as a change in electric current. Since the change in dissolved oxygen concentration is a result of the glucose oxidation, the glucose concentration of the sample can be measured. The biosensor does not directly detect the target analyte (glucose). Instead, it measures the change in the concentration of a co-reactant (oxygen) or a co-product (hydrogen peroxide) of the reaction catalyzed by the immobilized biological-sensing material (i.e., GOD).

Biosensor configurations are categorized into two types; batch type (a) and flow type (b) as depicted in Fig. 17.3 (Buerk, 1993). In flow-type sensors, a bioreactor, a column stuffed with biomaterial-immobilized beads, can be incorporated separately from a transducer. Flow-type biosensors are very useful for continuous monitoring of target analytes. Immobilization of biomaterials is usually required for biosensor fabrication. Typical immobilization carriers are glass, alginate and artificial resin beads, and membranes.

Disposable biosensors such as amperometric glucose sensors for medical diagnosis are examples of a batch-type sensor. Flow injection analysis (FIA) is a technique sometimes used in flow-type biosensors. Because biosensors using FIA yield very rapid and accurate measurements, these have been applied to various fields, such as environmental monitoring and food quality control.

In a typical biosensor study, parameters such as the amount of immobilized biological-sensing elements (e.g., enzymes), pH, and temperature of the buffer are optimized, and then a calibration curve is generated using standard solutions containing known concentrations of the analyte. Figure 17.4 shows a typical calibration curve of a biosensor. Calibration curves are normally obtained by one of two methods: from reaction curves of the biological co-reaction measurement (Fig. 17.4a) or the biological co-product measurement

FIGURE 17.1 Biological elements are combined with transducers when biosensors are fabricated. Electrodes and optical devices are widely used as transducers in biosensors. A piezoelectric device such as a quartz crystal detects a weight change before and after the biological reaction as applied to immuno- and DNA sensors. Transducers convert a change in the concentration of the compound into an electronic signal.

FIGURE 17.2 Principle of a glucose sensor. The analyte is glucose, and the biological-sensing element of the biosensors is glucose oxidase (GOD). The membrane-immobilized GOD is combined with an oxygen electrode as a transducer. An oxygen electrode generates electric current depending on the dissolved oxygen concentration. Glucose and oxygen permeate into the membrane-immobilized GOD. (a) Dissolved oxygen is not consumed when a sample which does not contain glucose such as pure buffer solution is measured by the glucose sensor. The sample is air-saturated and the oxygen electrode produces stable high current. This value is defined as the baseline current of the sensor. (b) A sample containing glucose is measured by the glucose sensor. GOD catalyzes the glucose oxidation using oxygen and dissolved oxygen is consumed. The oxygen concentration is lower than that in (a) and the electric current decreases from the baseline current. (c) Typical reaction curve of the sensor is illustrated. A, the baseline current; B1–B3, the electric currents obtained from samples containing glucose. The differences between A and B1–B3 are the sensor responses (C1–C3). As glucose concentration increases, the sensor response will also increase.

(Fig. 17.4b). In both cases the sensor responses are calculated from the difference between the values of pure buffer and the sample containing the analyte.

The sensitivity of a biosensor is defined as the slope of the linear range of the calibration curve. The linear range is between the lower detection limit (C1) and the nonlinear profile at higher concentration (C6, –7,

FIGURE 17.3 Two types of biosensor measurements. The illustrated biosensor is a combination of an electrode and a membrane-immobilized biomaterial. For example, adsorption or entrapment methods may be used to immobilize biomaterials. The membrane with immobilized biomaterial such as cellulose acetate membrane (0.45 μm) is attached to the electrode by an O-ring. (a) Batch-type measurement. The biosensor is immersed in the buffer solution and the analyte solution is directly injected into the buffer solution. (b) Flow-type measurement. The biosensor is attached to a flow cell and a flow-type biosensor is fabricated. The buffer solution is propelled by a peristaltic pump and the analyte solution is injected into the flow line. The buffer solution mixed with the analyte is introduced to the flow cell and is measured by the biosensor.

and –8). The biosensor response (biosensor output signal R_s) obtained from the sample measurement is substituted into the calibration curve in Fig. 17.4 and the analyte concentration of the sample can be calculated (C_x).

Reproducibility and the life-time of a biosensor are usually examined, and selectivity must also be evaluated in some cases.

Biosensors have replaced conventional methods, which are often complicated, time-consuming, expensive, and require pretreatment or clean-up of real samples prior to analysis. Biosensors generally have the following advantages compared to other analytical methods:

1. Rapid and convenient detection.
2. Direct measurement of real samples.
3. Very specific detection.

On the other hand, stability and reproducibility have been problematic for biosensors due to the inherent instability of biomaterials used as sensing

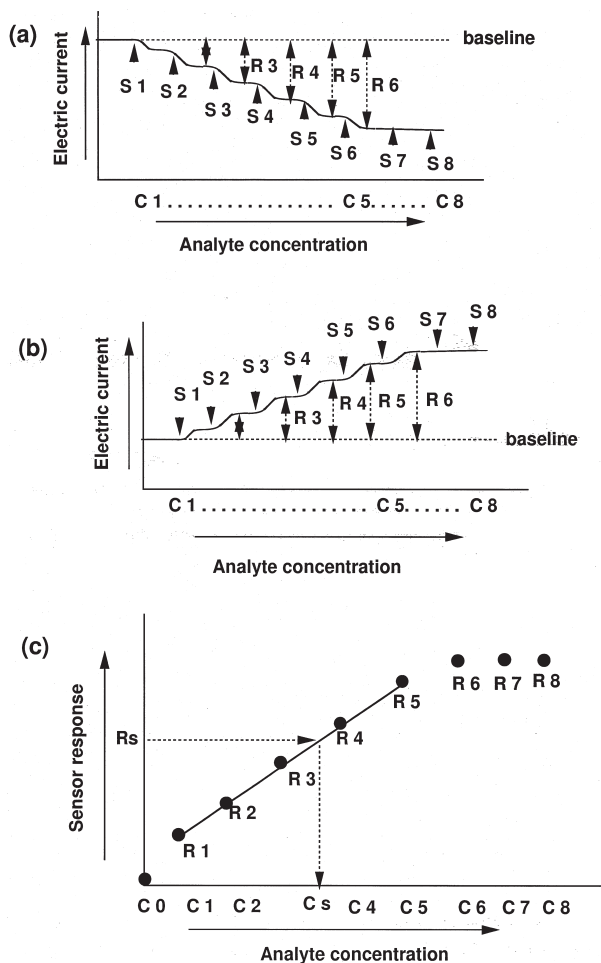

FIGURE 17.4 Typical calibration curve of a biosensor. The sample injections were carried out eight times (S_n). (a) A reaction curve of a biosensor based on the measurement of co-reactants. Co-reactant is consumed during the measurement and the sensor output such as the electric current in the figure decreases as the analyte concentration increases. The baseline current is higher than that of the sample containing the analyte. The sensor response (R_n) is calculated by subtracting the measurement value (e.g. the electric current) of the sample containing the analyte from the baseline value. (b) A reaction curve of a biosensor based on the measurement of co-products. Co-product or sensor output increases as the analyte concentration increases. The baseline value is less than that of the sample containing the analyte. The sensor response (R_n) is obtained by subtracting the baseline value from the measurement value of the sample containing the analyte. (c) A calibration curve. The dynamic range of a biosensor is the linear correlation from the detection limit C1–C5. The sensitivity of the biosensor, for example, is calculated as $(R_4 - R_2)/(C_4 - C_2)$. R_s is obtained when an unknown concentration sample is measured by the biosensor and it is substituted into the linear correlation, and the sample concentration C_s is obtained.

elements. Although biosensors have disadvantages, numerous investigations on biosensors to date have helped to overcome at least some of these difficulties, allowing practical application of many biosensors in the real world.

II. APPLICATIONS OF BIOSENSORS

Biosensors have been applied in many important fields, such as food quality control, environmental monitoring, and medical diagnosis. Recently, some groups reported biosensors for detecting chemical or toxic agents for use in military settings (Buerk, 1993). A few examples of biosensors in practical use in major fields are described in the following sections.

A. Food analysis

Many biosensors such as enzyme sensors have been developed for food analysis and food quality control. Enzyme sensors are used for the measurement of sugars, such as glucose, sucrose, and fructose. Vitamin C (ascorbic acid) and glutamate in food are also measured by biosensors. Some of these sensors are also being used in the medical field and for monitoring waste-water. Many of these sensors operate on the same principle as described previously for the glucose sensor shown in Fig.17. 2. The freshness of fish meat can also be measured by enzyme sensors. The freshness sensor that detects the degradation products of adenosine triphosphate (ATP) in fish meat, as well as many other enzyme sensors, achieves very high sensitivity by combining an FIA system coupled with chemiluminescence detection.

Microbial sensors are also applied to food quality analysis for measuring free fatty acids in milk (Schmidt *et al.*, 1996), alcohol, or acetic acid (Suzuki, 1990). The free fatty acid sensor uses *Arthrobacter nico-tianase*, and both the alcohol and the acetic acid sensors use same bacterium, *Tricosporon blassicae*.

B. Medical diagnosis

Enzyme sensors and microbial sensors for antibiotics and vitamins have been fabricated since the 1970s. Diabetes has been a particularly important target for many biosensors intended for medical use. Glucose sensors have been applied to diagnosis and monitoring of diabetes patients and to food quality analysis. Insulin biosensors have also been developed for use in diabetes treatment.

Since the first glucose sensor using an oxygen electrode was reported, numerous glucose sensors have been developed using techniques aimed at practical use. For example, screen-printing (Nagata *et al.*, 1995) and micromachining techniques (Hiratsuka *et al.*, 1998) have been applied to glucose sensors.

Disposable biosensors have very promising applications in medical diagnosis, such as monitoring blood glucose concentrations in diabetes patients.

Matsushita Company (Osaka, Japan) has commercialized a circular-type glucose sensor which utilizes semiconductor technology.

C. Environmental monitoring

Biosensors can rapidly detect and measure eutrophants, toxicants, and biochemical oxygen demand (BOD) in the environment. Enzyme immuno and microbial sensors have been mainly developed to detect pollutants in the environment. Biosensors for environmental monitoring have been reviewed (Karube *et al.*, 1995).

The phosphate sensor is a typical example of an enzyme sensor for environmental monitoring. In the past few years, dramatic improvements have been made in phosphate detection systems using enzyme sensors (Nakamura *et al.*, 1997), and it is expected that some of these sensors will be used in the field in the near future.

Many biosensors have been developed to detect toxicants in the environment such as pesticides and cyanide. Jeanty and Marty (1998) reported organophosphates detection systems based on acetylcholine esterase inhibition. Immuno-sensors, in place of conventional enzyme-linked immuno sorbent assays are also frequently used to detect pesticides. Carl *et al.* (1997) fabricated an immuno-sensor which detects chemical endocrine disrupters (PCB) using a screen-printing technique, and recently Seifert and Hock (1998) investigated a novel sensor which uses a human estrogen receptor and an SPR-detection system. Microbial sensors have been constructed which detect cyanide and detergents. Karube *et al.* (1995) reviewed developments in microbial sensors for environmental monitoring.

The BOD sensor, which uses an omnivorous yeast *Trichosporon cutaneum*, is a well-known example of a microbial biosensor applied to environmental

monitoring (Cass, 1990). The microbial BOD sensor measures the oxygen uptake by the respiratory system of the microorganism which changes as a result of the biodegradation of organic compounds in the sample. (Fig. 17.5). The microbial BOD sensor systems have been commercialized and marketed since 1983 by several companies (DKK, Nisshin Denki, and Central Kagaku Co., Tokyo).

III. CURRENT TOPICS IN BIOSENSORS

Enzyme-, immuno-, and microbial sensors have become very popular. Sensors that take advantage of new transducing techniques such as SPR and a charge-coupled device have increasingly been reported (Buerk, 1993). Novel molecular recognition elements, such as DNA oligomers having specific affinity to various target molecules, have also been tested for use in biosensors.

Stability of a biosensor is very important, especially when the sensors must be used continuously in the field. Microorganisms and few stable enzymes are suitable for this purpose. However, many enzymes and antibodies used in biosensors are not stable enough for long-term practical use. Molecularly imprinted polymers (MIPs) have been employed in place of antibodies to construct biosensors with enhanced stability (Kriz *et al.*, 1995). These polymers are prepared by polymerization of various monomers in the presence of the target compound which acts as a template. After the polymer is removed from the template compound, the polymer retains the memory of the template and can selectively rebind the template compound. The use of MIPs to replace biomolecules in biosensors has advantages such as enhanced stability and inexpensive cost, which may expand the scope and applicability of the biosensors of tomorrow.

ACKNOWLEDGMENT

We thank Yohei Yokobayashi at The Scripps Research Institute for his help and advice in preparing the manuscript.

Cell membrane: structure and function

Robert J. Kadner

University of Virginia

GLOSSARY

ABC proteins Proteins that contain the widely conserved ATP-binding cassette, a motif that couples energy from ATP binding and hydrolysis to various transport processes.

detergent A molecule with polar and nonpolar portions that can disrupt membranes by stabilizing the dispersion of hydrophobic lipids and proteins in water.

hydrophobic Molecules or portions of molecules that cannot form hydrogen bonds or other polar interactions with water.

hydrophobic effect The tendency of hydrophobic regions of molecules to avoid contact with water.

osmolarity The tendency of water to flow across a membrane in the direction of the more concentrated solution.

proton motive force The electrochemical measure of the transmembrane gradient of protons, consisting of an electrical potential due to separation of charge and the pH gradient due to different concentration of protons.

symporter A transport system in which movement of the coupling ion moves in the same direction as the substrate molecule, in contrast to an antiporter or uniporter.

Every Cell Possesses a Surface Membrane that separates it from the environment or from other cells. Animal cells

and other eukaryotic cells possess, in addition to the plasma membrane, numerous intracellular membranes which form the organelles that perform specialized metabolic functions. Bacterial and archaeal cells typically lack intracellular membrane organelles and contain only the single cytoplasmic membrane, perhaps surrounded by an outer membrane. The cytoplasmic membrane of bacteria is typically composed of simple phospholipids that form a membrane bilayer, into which are inserted a large number of different proteins. The phospholipid bilayer forms the osmotic barrier that prevents movement of most materials into or out of the cell. The various membrane proteins carry out numerous important functions, including the generation and storage of metabolic energy and the regulation of uptake and release of all nutrients and metabolic products. Membrane proteins recognize and transmit many signals that reflect changes in environmental conditions and trigger an appropriate cellular response. They also play key roles in the control of cell growth and division, bacterial movement, and the export of surface proteins and carbohydrates.

I. ULTRASTRUCTURE AND THE ROLE OF CYTOPLASMIC MEMBRANE

A. Ultrastructure of cell membranes

Cell membranes are readily visible when thin sections of cells are stained with heavy metals and viewed in

the electron microscope. They appear as a characteristic triple-layered structure with two dark electron-dense layers, representing the region of the lipid head groups, surrounding a light layer which reflects the hydrophobic central portion of the membrane bilayer. All cellular membranes appear quite similar by this technique, regardless of the source of the membrane or their protein content (Fig. 18.1a). Most biological membranes are 4 or 5 nm in width. In the technique of freeze-fracture electron microscopy a knife blow is used to split a frozen sample of cells. The fracture plane often extends along or through the weakly connected central section of a membrane bilayer. This technique can reveal the presence and density of proteins embedded in and spanning through the membrane. Figure 18.1 supports the fluid mosaic model of membrane structure in which the polar membrane lipids form a lamellar, or leaf-like, bilayer in which their nonpolar portions face each other in the central region and their polar regions are on the outside. Integral membrane proteins span across the bilayer, but can diffuse within the plane of the bilayer and even associate into large complexes. Many peripheral membrane proteins do not span across the membrane and can be transiently bound through hydrophobic anchors or by association with other membrane proteins or the lipid head groups.

B. Role as osmotic barrier

The cytoplasmic membrane is the osmotic barrier of the cell, owing to its ability to restrict the passage of salts and polar organic compounds. If a cell is placed in a medium in which the osmolarity is higher or lower than the osmolarity of the cytoplasm, water will flow across the cytoplasmic membrane out or into the cell, respectively. This osmotic flow of water occurs in response to the natural forces that seek to eliminate gradients or differences in the concentration of water on the two sides of the membrane. Hence, the cytoplasm either shrinks or swells under these two conditions as a result of the loss or gain of water. In most bacteria, the cell does not change size owing to the presence of its rigid cell wall.

C. Role as cell boundary

The cytoplasmic membrane is the boundary between the cell and its surroundings and thus must regulate the passage of nutrients and metabolic products. The presence of the hydrophobic layer formed by the membrane lipids greatly restricts the passage of any polar molecules and of macromolecules. It prevents

FIGURE 18.1 Structure of bacterial membranes. (a) Electron micrograph of a thin section of the fish pathogen, *Aeromonas salmonicida*. Cells were embedded in plastic, cut to a thin slice, stained with heavy metals (uranyl acetate and lead citrate), and visualized by transmission electron microscopy. The cytoplasmic membrane is seen as the triple-layered structure bounding the cytoplasm. Outside the 7.5-nm thick cytoplasmic membrane is the periplasmic space, the triple-layered outer membrane, and the thick surface S layer. (b) Electron micrograph of a freeze-fractured sample. A suspension of cells of *Bacillus licheniformis* was frozen, and the block was shattered by a sharp blow with a knife edge. The fracture plane ran occasionally through membrane bilayers. A carbon replica of the two faces thus revealed was made, the organic material was etched away with acid, and surface structures were enhanced by shadowing with a beam of platinum atoms. The image is viewed in transmission electron microscope. The two faces show the two halves of the cytoplasmic membrane layer, indicating the presence of particles that are embedded in and span the membranes (courtesy of Terrance Beveridge, University of Guelph, Canada).

the loss of cellular macromolecules and metabolic intermediates.

D. Regulation of transport

Transport systems allow the passage of specific molecules, such as ion, nutrients, and metabolic products, either into or out of the cell. Bacteria in general have a large number of very specific transport systems that carry out active transport. They consume some form of metabolic energy to be able to pump their substrate from a low concentration on one side of the membrane to a much higher concentration on the other side. Transport is an integral part of the universal process of bioenergetics, which refers to the formation and consumption of sources of cellular energy, most of which involve transmembrane ion gradients.

E. Role in cell growth and division

Expansion of the membrane surface is intimately related to growth rate of any cell, and all components must be inserted in a timely manner to allow cells to expand in size. Cell division requires a carefully controlled process whereby the membranes of the parental cell pinch together, fuse, and separate to create two progeny cells, without loss of internal material. The membrane contains export systems of control the release of structural components to the cell surface and other secreted factors beyond the cell. Other membrane-localized protein complexes regulate the process of initiation of DNA replication, separation of chromosomes into the dividing bacterial cells, and in-growth of the cell surface that occurs during cell division.

II. STRUCTURE AND PROPERTIES OF MEMBRANE LIPIDS

A. Lipid composition

The key ingredients of biological membranes are polar lipids, primarily phospholipids. In most bacteria, phospholipids consist of two fatty acids, usually with 16–18 carbon atoms in the hydrocarbon chain with zero or one *cis*-double bond. The fatty acid content changes in response to environmental conditions, particularly temperature. As described later, lower growth temperatures result in a higher degree of fatty acid unsaturation, which has dramatic effects on the membrane's fluidity and function. Some fatty acids are branched or contain cyclopropane rings. Fatty acids are joined in ester linkage to two of the hydroxyl

groups of glycerol, usually with a saturated fatty acid at the 1-position and an unsaturated fatty acid at the 2-position. To the third hydroxyl group of glycerol is attached a phosphate moiety and to it the head group. In bacteria, the range of head groups is narrow, and the phospholipids in *Escherichia coli* are approximately 75% phosphatidyl ethanolamine (PE) and 20% phosphatidyl glycerol (PG), and the remainder is cardiolipin (diphosphatidyl glycerol), phosphatidyl serine, and trace amounts of other phospholipids (Fig. 18.2).

Other bacteria possess more complex types of membrane lipids, although these lipids are usually much less complex than those in the plasma membrane of animal cells. Some bacteria possess phosphatidyl choline, or lecithin, which is characteristic of higher organisms. Other bacteria produce glycolipids, such as monogalactosyl diglyceride. The membrane lipids from archaea are quite different from those in bacteria and eukarya. Their hydrocarbon chains are based on isoprenoid units and these are linked to the glycerol backbone in an ether, rather than ester, linkage. In some archaea, a glycerol backbone and head group are attached to both ends of a pair of isoprenoid units.

Sterols, such as cholesterol in mammalian cells or ergosterol in fungi, are invariant features of membranes in eukaryal cells, in which they appear to stiffen the membrane by increasing the degree of order of the hydrocarbon chains. Sterols are not commonly found in bacteria and archaea, except for the cell wall-less *Mycoplasma*. Very complex lipids, including the very long, branched mycolic acids, are common in *Mycobacterium* but occur in a very thick and rigid outer layer rather than in the cytoplasmic membrane.

B. Hydrophobic effect

Phospholipids spontaneously form membranous structures when suspended in aqueous solution. The forces that drive their assembly into a bilayer or more complex structure are called the hydrophobic effect. This organizing force depends on the ability of water molecules to donate and accept hydrogen bonds from one another to form an extensive network of water molecules transiently linked through hydrogen bonds and polar interactions. Polar molecules can participate in this interactive network of water molecules and are thereby able to dissolve in aqueous solution. In contrast, hydrophobic or nonpolar molecules, such as a long hydrocarbon or aromatic chain, are unable to participate in the hydrogen-bonded network of water molecules. For them to dissolve in water would result in loss of the energy resulting from the intrusion in the mobile water bonding and from the organization of

FIGURE 18.2 Chemical structures of the fatty acids and phospholipids that comprise the bulk of the membrane lipids in *E. coli*. For the phospholipids, the R groups represent a fatty acid.

water molecules into a cage-like structure around the intruding nonpolar molecule. It is the loss of the energy of interaction between the water molecules and the entropic cost of organizing them that drive the nonpolar molecules to associate with one another, out of contact with the water. Hence, non-polar lipids tend to form oil droplets in water, so as to present the smallest possible hydrophobic surface to the water.

C. Membrane bilayer

Polar lipids, such as phospholipids, have chemical structures of two different natures. The hydrophobic acyl chains strive to be sequestered from contact with water, whereas the charged and polar head groups seek contact with aqueous ions to help dissipate their electrical charge and to form a hydrogen-bonded network with water. Thus, polar lipids are driven by basic physical characteristics to form aggregate structures in which the hydrophobic portions are segregated out of contact with water while the head groups face

the water. There are numerous ways in which these requirements can be accommodated. Of greatest biological relevance is the lamellar bilayer, in which large flat surfaces of bilayer form with the acyl chains facing each other on the inside and the head groups facing the solution on the outside (Figs. 18.3 and 18.4). Other nonlamellar structures, such as hexagonal phases, can form under certain conditions of head group, temperature, and salt concentration. The propensity of different lipids to form nonlamellar bilayers is a function, in part, of the relative cross-sectional areas of the hydrophobic acyl chains in reference to the area of the head group. When the areas of the polar and nonpolar parts are similar, a lamellar bilayer is favored. If the nonpolar part is substantially smaller or larger than the head group, formation of a spherical micelle or an inverted structure, such as the HexII phase (hexagonal phase II), respectively, is favored.

When most biological phospholipids are dried into a film from a solution in an organic solvent and then water is added, the lipids spontaneously form a

FIGURE 18.3 Schematic representation of the lipid bilayer or lamellar arrangement. The polar head groups of the lipids face the water, and the hydrocarbon acyl chains are segregated away from the water in the interior of the bilayer.

multilamellar liposome in which concentric bilayers assemble like an onion. When these liposomes are sonicated (disrupted by intense ultrasonic irradiation), they break down into small unilamellar vesicles. These are small spherical particles with a single membrane bilayer surrounding an aqueous cavity.

D. Lipid phase behavior

Above a certain temperature, the lipid molecules in a bilayer can move rapidly within the plane of the membrane but do not move very far in or out of the membrane owing to the hydrophobic effect. In this liquid crystalline state, the acyl chains are parallel to each other but undergo frequent rotations around the carbon bonds to produce kinks in the chain. These kinks provide transient discontinuities in the hydrophobic barrier that allow movement of other lipid molecules within the membrane and of water molecules across the membrane. As the suspension of membranes is cooled below a critical temperature (T_m), there is a transition of the lipids from the liquid crystalline phase to the rigid gel phase. In this phase, all the hydrocarbon chains form the *all-trans* configuration, which increases the bilayer thickness and greatly decreases diffusion of the lipids within the membrane and of permeants across the membrane. This transition reflects the motion and packing of the acyl chains.

The critical temperature at which the gel-to-liquid crystalline phase transition occurs is dependent on the

FIGURE 18.4 Representation of the orientation of the acyl chains and head groups of a phospholipid in a bilayer. This orientation of phosphatidylethanolamine is seen in crystal structures. The solid circles represent oxygen atoms; the heavy lines represent the glycerol; the thin lines are ethanolamine; and the gray lines are the hydrocarbon chains of the two fatty acids, all in their most extended configuration.

lipid composition, including the nature of the head group and the lipid chains. The longer the hydrocarbon chains, the higher the T_m for transition to the liquid crystalline state. The presence of unsaturated fatty acids with one or more double bonds has a very dramatic effect reducing the T_m by as much as 60°C. The effect of the double bond is greatest when it is in the middle of the acyl chain. The double bond introduces a permanent kink or bend in the chain that interferes with packing of the chains in the gel state. Most cells adjust their lipid composition to the growth temperature to ensure that their membrane remains in the liquid crystalline state. Most membrane proteins are excluded from or are inactive in the rigid gel phase membranes. Another lipid phase transition can occur at temperature higher than T_m . This corresponds to the change of certain lipids from a lamellar to a nonlamellar configuration.

III. STRUCTURE AND PROPERTIES OF MEMBRANE PROTEINS

Although the lipids are very important for determining the barrier functions of the cell membrane, the membrane proteins confer most of the important functions of biological membranes. There are many different types of membrane proteins, reflecting their very different functions. Integral membrane proteins are those that cross the membrane with one or more transmembrane segments and are usually exposed to both sides of the membrane. They cannot be easily removed from the membrane unless detergents are added to disrupt the bilayer structure. Some integral membrane proteins are stably anchored to the membrane, usually by covalent attachment to a lipid such as a fatty acid, isoprenoid, phosphatidyl inositol, or a lipoprotein derivative. The membrane-spanning proteins include most of the functionally important transporters and signal receptors. Peripheral membrane proteins are defined operationally as those that are readily removed from association with the membrane by procedures that do not disrupt the bilayer, such as washing with high salt, urea, or sodium carbonate at pH 11. These proteins generally lack transmembrane segments, although it is recognized that some peripheral proteins can transiently insert a segment across the membrane as part of their normal function.

Some integral membrane proteins possess one or two transmembrane segments only, and the bulk of these proteins is located in the aqueous solutions on one or both sides of the membrane. The nonmembranous segments of these proteins are similar in character to that of a normal soluble globular protein. Charged or polar amino acid residues line the surfaces exposed to the water, and nonpolar amino acid residues form the interior of the domain, driven into this sequestered state by the same hydrophobic effect that stabilizes the membrane lipid structure. The membrane-spanning portion of these proteins has a very limited range of composition and structures. Owing to the very hydrophobic environment of the interior of the membrane bilayer, the presence of charged or polar residues or of unpaired hydrogen bonds is energetically unfavorable. Thus, the amino acid residues that comprise single transmembrane segments are generally highly hydrophobic. In addition, an α helix is the only peptide conformation in which all the hydrogen bonding possibilities of the polypeptide backbone are satisfied. Thus, single or double transmembrane segments are most likely to be non-polar α -helical segments, with lengths of approximately 20 amino acids

(approximately six turns of the helix), which is sufficient to span the width of the membrane.

Many membrane proteins cross the membrane multiple times and insert the bulk of their mass within the membrane. Transport proteins typically have 10–14 transmembrane segments, and a major class of signal receptors have seven transmembrane segments. These proteins have a very different character than that of the multidomain bitopic proteins described previously. The large surface of the protein that is imbedded in the membrane and exposed to the hydrophobic environment of the hydrocarbon lipid chains is highly hydrophobic and cannot possess charged amino acid residues. Other surfaces of these proteins are exposed to the solution on either side of the membrane. These surfaces, which are composed of the loops joining transmembrane segments, must possess mainly polar residues capable of remaining soluble in water. The presence of the very different surfaces of membrane proteins, two polar belts and one very nonpolar belt, holds the protein tightly within the membrane bilayer and restricts its movement out of the membrane.

The transmembrane segments of such a polytopic protein are α -helical in the few proteins for which detailed structural information is available (the photosynthetic reaction center, some electron transport complexes, bacteriorhodopsin, the vitamin B12 transporter, and lactose permease). The amino acid residues that comprise transmembrane segments need not be all nonpolar. These residues can be exposed to different environments, namely the lipid hydrocarbon chains, the neighboring α -helical transmembrane segments, and a potential water-filled channel. Thus, the residues of these transmembrane segments exhibit periodic variability, with very non-polar residues along one face and generally polar residues along the opposite face. In contrast, the transmembrane segments of most bacterial outer membrane proteins are composed of anti-parallel β sheets of approximately eight amino acid residues in length.

Proteins are inserted in cellular membranes in a defined orientation. The orientation of the entire protein appears to be determined by the orientation of its individual transmembrane segments. The orientation of each transmembrane segment is determined mainly by the nature of the charged residues flanking the transmembrane segment rather than by the residues within the transmembrane segment. The “inside-positive” rule seems to govern the orientation of transmembrane segments in bacteria, and it states that relatively short, positively charged loops are retained on the cytoplasmic side of the membrane. The orientation of a protein can be affected by its association with other cellular or

membrane proteins or by the presence of a signal sequence that directs the protein into the secretory pathway.

The orientation of a membrane protein can be determined experimentally by detecting the sites of action of proteases or other enzymes added to one side of the membrane. A simpler and more generally informative approach makes use of fusions of a part of the tested protein to a topological reporter, which is an enzyme whose activity depends on which side of the membrane it resides. It has thus been possible to gain a considerable degree of understanding of the structure of many membrane proteins, even without high-resolution crystallographic information.

IV. FUNCTIONS OF CYTOPLASMIC MEMBRANE

The cytoplasmic membrane of bacteria is a very busy site at which an almost bewildering number of important processes occur. It carries out most of the reactions that are handled by the many organelles of eukaryotic cells. Since bacteria are generally far more metabolically capable and diverse than eukaryotic cells, it is not surprising that an estimated one-fourth of the cell's proteins are membrane associated.

One of the key principles in biology is the basic universality of bioenergetics, which refers to the processes of energy generation, storage, and utilization in cells. The major feature of these processes is the use of ion gradients that are formed across cellular membranes, such as the membranes of mitochondria and chloroplasts in higher organisms or the cytoplasmic membrane of bacteria. In most systems, the gradient of protons is the central factor in bioenergetics, although gradients of sodium ions are used by some bacteria for energy generation and by most eukaryotic cells for cellular signaling and nutrient transport. The chemiosmotic proposal, initially made by Peter Mitchell, that ion gradients are the intermediate between the processes of electron transport and the formation of ATP has been overwhelmingly accepted. In bacteria, ion gradients are also used to drive several types of active transport systems, bacterial motility, and protein secretion.

A. Energy generation

Energy generation refers to the trapping in a metabolically useful form of the energy absorbed from sunlight or released by reduction of some inorganic molecule or the oxidation or breakdown of an organic molecule serving as energy source. Bacteria can generate

energy by many different processes. In simple fermentative pathways, such as the glycolytic breakdown of glucose to lactate, ATP can be formed during several enzymatic steps by the process of substrate level phosphorylation. Important energy-producing processes use electron transport chains to pass electrons from a carrier of high negative redox potential to carriers of successively lower energy states. During respiration, electrons enter these chains following transfer from an organic molecule and are ultimately transferred to an inorganic electron acceptor. During photosynthesis electrons are excited to a higher energy state following absorption of light by a chlorophyll-related molecule. Figure 18.5 summarizes several key steps of microbial energy generation.

During the processes of electron transport to carriers of successively higher redox potential, there is a separation of charge across the membrane. This is ultimately coupled to the movement of protons from one side of the membrane to the other, resulting in the formation of a proton motive force (pmf) which has two aspects. Movement of the positively charged proton creates an electrical charge across the membrane, which is termed $\Delta\psi$. In bacteria and mitochondria, in which electron transport results in the release of protons, the electrical charge is negative inside and can be 100–200 mV. Proton pumping also results in a difference in proton concentration, or ΔpH , across the membrane, such that the exterior is usually more acidic than the interior. Photosynthetic or respiratory electron transport thus results in proton pumping and creation of the pmf.

The proton gradient can be tapped to bring about the formation of ATP, which is the ultimate energy source for most energy-requiring processes in the cytoplasm. Synthesis of ATP is carried out by a family of protein complexes, which include the F_1F_0 proton-translocating ATPases of mitochondria and bacteria. Related complexes are found in chloroplasts and archaea. These protein complexes contain a membrane-embedded sector, the F_0 portion, which includes the pathway to allow the protons to flow back into the cell in response to the chemical and electrical forces acting on them. The F_1 portion of the complex contains the sites for conversion of $\text{ADP} + \text{P}_i$ to ATP, and the energy for this process is coupled to the movement of protons. The stoichiometry of the process is such that entry of three or four protons results in the formation of one molecule of ATP. The individual steps of proton movement through the F_1F_0 -ATPase and ATP synthesis or hydrolysis are tightly coupled under most conditions to prevent wasteful loss of the pmf or of the ATP pool in the cell and consequent heat generation. In bacteria, this ATP synthase can

FIGURE 18.5 Summary of some processes of generation of metabolic energy in bacteria. (Left) Components of respiratory electron transport chains, in which specific substrate dehydrogenases oxidize their substrate, transfer the released electrons to membrane quinones, and in some cases extrude protons to the exterior. The electrons of the reduced quinones are transferred by the terminal oxidase or reductase to the terminal electron acceptor, such as oxygen, with the extrusion of additional protons. (Bottom) Photosynthetic systems whereby absorption of light is converted to a transmembrane gradient of protons. (Right) Two examples in which substrate/product exchange and metabolism result in generation of pmf. (Top) The electrical and chemical components of the proton motive force and a representation of the action of the F_1F_0 -ATP synthase which interconverts the proton gradient and ATP synthesis or hydrolysis.

function in a reversible manner to allow ATP that was generated by substrate-level phosphorylation to drive formation of a proton gradient which can then be used to drive transport systems or motility. Movement of protons causes the F_0 sector to rotate within the membrane, like the action of a turbine. The rotation of the F_0 sector is coupled to changes in the conformation of the nucleotide-binding sites in the stationary F_1 sector, which is linked to interconversion of ADP + Pi to ATP.

1. Photosynthesis

Photosynthesis traps the energy of sunlight and converts it into metabolically useful forms such as ATP during cyclic electron transport and NADPH during noncyclic electron transport processes. In some organisms, photosynthetic electron transport is coupled to the formation of oxygen from water—the process that is essential for aerobic life. There are numerous

pigments in cells that absorb light energy for use in photosynthesis, but the most important of these are the chlorophylls. Chlorophylls are porphyrin molecules, similar to heme, but containing a magnesium atom instead of iron. Some pigments are carried in protein molecules that serve as antennae or light-harvesting complexes, but the key processes occur in a protein complex called the photosynthetic reaction center, which typically consists of three proteins that spread across the membrane and contain bacteriochlorophyll, bacteriopheophytin, menaquinone, and nonheme iron as electron carriers. The light energy is ultimately absorbed by a chlorophyll molecule and this energy excites an electron to a higher energy level. This excited electron passes through a series of electron-carrying prosthetic groups within the reaction center and then out through the pool of membrane-bound quinones, which transfer the electron to a cytochrome-containing electron transport chain. Passage of the electron through the electron transport

chain is coupled to pumping of protons across the specialized membranes containing the photosynthetic apparatus. In cyclic phosphorylation, as carried out in the photosynthetic bacteria, the electron ultimately returns to the chlorophyll molecules after transfer to the periplasmic heme protein, cytochrome *c*. In the process of noncyclic phosphorylation in plants and cyanobacteria, the electron can be transferred ultimately to pyridine nucleotides for use as a reductant in biosynthetic processes. In this process, the electron can be replaced on chlorophyll by another light-absorption process that removes electrons from water to create oxygen.

A completely different system for conversion of light into metabolic energy is present in *Halobacterium salinarum*, an extremely halophilic archaeon that thrives in very saline environments such as the Dead Sea or brine evaporation ponds. These bacteria produce patches of membrane that are densely packed with the membrane protein, bacteriorhodopsin, having seven transmembrane helices and covalently bound retinal as in the visual pigment in mammalian retina. Light absorption by the retinal causes the isomerization of one of the double bonds in the molecule, causing a change in the conformation of the protein which results in the change of the *pK* of several acidic groups on either side of the membrane. The consequence of these changes is that a proton is released from the bacteriorhodopsin on the outside of the membrane and replaced by one from the cytoplasm. In this way, light is directly converted into a transmembrane proton gradient without the requirement of an electron transport chain.

2. Respiration

Respiration is the process whereby electrons from the metabolism of an energy source are transferred through a proton-pumping electron transport chain to some inorganic molecule. The most familiar form of respiration is aerobic respiration, in which oxygen serves as the ultimate electron acceptor. Owing to the ability of oxygen to accept electrons, aerobic respiration is the most energetically favorable, but some partially reduced forms of oxygen, hydrogen peroxide, superoxide anion, and hydroxyl radical, are extremely reactive and thus toxic to the organism. Many bacteria are capable of carrying out anaerobic respiration, in which the electrons are transferred to alternative acceptors, such as nitrate, nitrite, sulfate, or sulfite. These processes yield less energy but can occur in anoxic environments.

All respiratory metabolism uses electron transport chains, whereby electron transfer from the donor to

oxygen or other acceptor is coupled to proton movement across the membrane. In *E. coli*, electron donors for respiration include NADH, succinate, glycerol 3-P, formate, lactate, pyruvate, hydrogen, and glucose. Electron acceptors include oxygen, nitrate, nitrite, fumarate, dimethylsulfoxide, and trimethylamine-*N*-oxide. Typical respiratory systems contain two to four transmembrane protein complexes. These include substrate-specific dehydrogenases, which transfer electrons from the donor to quinones in the membrane. The reduced quinones migrate to another protein complex which accepts electrons from them and transfers the electrons to cytochromes and ultimately to the terminal electron acceptor. The transmembrane protein complexes often contain flavin and/or non-heme iron and are arranged in the membrane in such a way that the passage of electron results in the release of proton to the outside or its consumption from the cytoplasm, i.e. the formation of the pmf.

3. Coupled processes

Some bacteria couple the transport and metabolism of their energy source directly to the production of the pmf. An example of this very simple, but not very energy-rich, process is malolactate fermentation in *Leuconostoc*. The substrate malate is transported into the cell and converted to lactate, which leaves the cell in exchange for a new molecule of malate. The net result of this process is the movement of one negative charge into the cell and the consumption of one proton inside the cell, which results in the creation of a pmf that is interior negative and alkaline.

B. Membrane transport

Biological membranes form the permeability barrier separating the cell from its environment. The hydrophobic barrier of the membrane bilayer greatly restricts passage of polar molecules, although non-polar molecules can pass. Transport mechanisms exist to move nutrients and precursors into the cell and metabolic products, surface components, and toxic materials out of the cell. Several types of transport mechanisms and families of transporters have been identified.

1. Types of transport systems

Transport can occur through energy-dependent and energy-independent processes. Several general classes of transport process have been identified. Passive diffusion occurs spontaneously without the involvement of metabolic energy or of transport proteins. It only allows the flow of material down a concentration

gradient, and the rate of this process is a linear function of the concentration gradient. The rate of passive diffusion depends on the ability of the permeant to dissolve in the membrane bilayer and thus depends of the polarity of the permeant and its size. These factors are related to the ability of the permeant to fit into transient defects that form in the membrane bilayer. Only water and a few hydrophobic molecules use this mechanism for entry into bacteria.

Facilitated diffusion requires the operation of a membrane protein for passage of the permeant across the membrane. These transporters merely provide a route for diffusion of their substrate down its concentration gradient, and thus the concentration of the substrate on both sides of the membrane will become equal. Transport is not dependent on the polarity of the substrate and usually exhibits stereospecificity, in which isomeric forms of the same compound are transported at very different rates. Because of the involvement of the transporter as a catalyst for movement, the rate of transport can be saturated in the same manner as an enzyme-catalyzed reaction. A possible example is the glycerol facilitator GlpF of *E. coli*, a transmembrane protein that allows glycerol and other small molecules to diffuse across the cytoplasmic

membrane at rates much faster than they cross lipid bilayers. However, this protein may act in the manner of a channel rather than a carrier.

The overwhelming majority of transport systems in bacteria catalyze active transport and expend metabolic energy to allow the accumulation of even very low external concentrations of a nutrient to a much greater concentration inside the cell. Active transport is carried out by a transport protein or complex and thus exhibits substrate stereospecificity and rate saturation. The difference compared to facilitated diffusion is that the substrate can be accumulated at concentrations as much as 1 million times higher than that outside. This accumulation requires the expenditure of energy, and in the absence of energy many but not all transport mechanisms can carry out facilitated diffusion. These active transport systems differ in their molecular complexity and in the mechanism by which metabolic energy is coupled to substrate accumulation. It is important to distinguish active transport, in which the substrate is accumulated in unaltered form, from group translocation, in which the substrate is converted into a different molecule during the process of transport. Some types of transport processes in bacterial cells are summarized in Fig. 18.6.

FIGURE 18.6 Schematic representation of several types of active transport systems in bacteria. Top, transporters linked to the pmf; left, ATP-driven transports; bottom, examples of systems that carry out release of metabolic products of toxic chemicals. (Right) A presentation of all the transport systems known to mediate uptake or release of potassium in *E. coli*. Some of these transporters are ATP driven; others are coupled to the pmf; and MscL is a channel activated by mechanical stretch of the membrane.

2. *ATP-driven active transport*

Several groups of transport mechanisms use the energy gained during ATP hydrolysis to drive active transport. One of these groups is called the P-type ion-translocating ATPases to indicate the fact that a phospho-enzyme is formed as an intermediate in their reaction cycle. Typically, these transport systems consist of a large polypeptide of approximately 100 kDa which spans the membrane and contains the site for ATP binding and the residue that is phosphorylated. A smaller subunit usually participates in the activity. The ATP is used to phosphorylate a specific acidic aspartate residue, and this phosphorylation causes a change in conformation of the transporter that is part of the ion pumping process. Several examples of this type of transport system have been extensively studied. The sodium/potassium ATPase in the plasma membrane of higher organisms is responsible for pumping sodium out and potassium into cells, thereby generating the ion gradients that are necessary for many steps of nutrient transport and for neural signal transmission. The electrical potential that exists across the plasma membrane of mammalian and some other cells is based mainly on the difference in sodium ion concentration that is maintained by the action of this transporter. Similarly, the calcium-translocating ATPase located in the sarcoplasmic reticulum acts to lower the intracellular calcium concentrations that accumulate following the processes that initiate muscle contraction. Other P-type ATPases include the proton-translocating ATPase in the plasma membranes of fungi and plants, which establishes the gradient of protons that is used to drive many of these cells' nutrient transport systems, and some of the transport systems for magnesium or potassium ions in bacteria.

Although P-type ATPases function only in the transport of ions, another family of ATP-driven systems transports a wide range of substrates and is involved in the uptake of numerous types of nutrients and in the efflux of both surface and secreted macromolecules (proteins, carbohydrates, and lipids) and of toxic chemicals. This family of transporters is usually the largest family of any set of related genes in those organisms whose genomes have been completely sequenced. Although the subunit composition of these transporters differs, they are called the ABC family to indicate the presence in at least one subunit of a highly conserved ATP-binding cassette, a protein domain that couples ATP binding and hydrolysis to the transport process. A more descriptive name for these proteins is traffic ATPases.

One subset of the family of ABC transporters includes a large group of nutrient uptake mechanisms

present only in bacteria and archaea and called periplasmic permeases. These transport systems, such as those for histidine, maltose, oligopeptides, etc., consist of a heterotetramer in which two highly hydrophobic transmembrane proteins with usually five or six membrane-spanning segments are associated with two subunits that contain the ATP-binding cassette and are mainly exposed to the cytoplasm. A fifth protein subunit is responsible for the substrate specificity of these transport systems. This substrate-binding protein usually has very high affinity for the substrate and allows uptake of nutrients even in nanomolar-range concentrations. The structure of these substrate-binding proteins resembles a clam, with two large lobes hinged in the middle. The substrate binds to specific residues in both lobes, which close around the substrate molecule for carriage to the membrane-bound components and entry into the cell. In gram-negative bacteria, the substrate-binding protein floats freely in the periplasmic space between the cytoplasmic and outer membranes. Gram-positive bacteria lack the outer membrane and, to prevent its loss, the binding protein is tethered to the cytoplasmic membrane by a lipoprotein anchor. The mechanism by which ATP hydrolysis is coupled to the release of substrate from the binding protein and its movement across the membrane is currently being studied. A striking feature of these transporters is that they act in a unidirectional manner and only allow nutrient to enter the cell but not to be released.

The basic features of the ABC transport process and homologous transport components also operate in the opposite direction in many processes of macromolecular export, including proteins and surface carbohydrates.

3. *Transporters coupled to ion gradients*

In addition to ATP-driven active transport systems, bacteria possess many transporters in which the movement of their substrate is obligately coupled to the movement, in the same or opposite direction, of an ion. In this way, accumulation of a substrate is coupled to the expenditure of the gradient of the coupling ion, which is usually a proton or sodium ion. Transmembrane ion gradients are a very convenient source of energy for active transporters. Entry into the cell of at least three protons must occur for synthesis of one molecule of ATP. It is thus very economical for the cell if it can accumulate a molecule of substrate at the expenditure of one proton rather than having to expend one ATP molecule for the same purpose. Symport refers to the process in which the coupling ion moves in the same direction as the substrate, that is, when the downhill movement of a proton into the

negative and alkaline interior of the cell is coupled to the uptake of substrate. Antiport is the reverse process, in which the two molecules move in opposite directions. If movement of substrate is coupled to movement of a proton in a 1:1 stoichiometry, then a pmf of -120 mV can achieve a 100-fold accumulation of substrate inside the cell. A pmf of -180 mV can allow a 1000-fold gradient of substrate. Uniporters allow coupling of the movement of a positively charged molecule to the pmf without movement of any other ion. The cationic molecule is drawn into the negatively charged cell interior simply by electrostatic attraction.

These types of transporters are referred to as secondary active transport systems since they use the pmf that was generated by other means and do not use an immediate source of energy, such as ATP. Ion-coupled transport systems are inhibited by conditions that dissipate or prevent formation of the pmf, such as ionophores which allow ions to distribute across the membrane in response to the electrical and chemical gradients that act on it. An uncoupler or protonophore, such as 2,4-dinitrophenol or carbonylcyanide *p*-trifluoromethoxy phenylhydrazone, is a hydrophobic molecule that can cross the membrane in either its ionized or its neutral form. Its presence allows protons to equilibrate across the membrane, thereby dissipating both the electrical and the chemical gradients of protons and thus the entire pmf. The ionophore valinomycin carries potassium ions and allows them to distribute across the membrane in response to electrical or chemical gradients. The addition of valinomycin to cells or membrane vesicles that have a pmf allows potassium ions to accumulate inside the negatively charged interior. This accumulation results in dissipation of the electrical potential $\Delta\psi$. The ionophore nigericin carries protons and sodium or potassium ions across the membrane, but only in the process of exchange. The action of nigericin thus does not result in any net gain or loss of charge and thus does not dissipate $\Delta\psi$. However, if there is a concentration gradient of protons, ΔpH , nigericin allows the concentration gradient to dissipate, whereas the electrical potential is maintained or even increased.

Ion-coupled transporters typically consist of a single polypeptide chain with 12 transmembrane segments, although examples with 10–14 transmembrane segments are known. It has been proposed that these proteins arose as the result of tandem duplication of a precursor protein with six transmembrane segments.

In the well-studied *E. coli* lactose permease LacY, several major experiments demonstrated the coupling of lactose accumulation to the pmf. The magnitude of the pmf affects the magnitude of the accumulation ratio of lactose inside the cell in a direct manner indicative of a

1:1 stoichiometry of lactose and proton. When membrane vesicles are energized by provision of a substrate for the electron transport system, a pmf is generated and lactose is accumulated. Even when a final steady-state level of lactose accumulation is reached, the lactose is in continual movement in both directions across the membrane. At the steady state, the rates in and out of the vesicle are equal, although the internal concentration of lactose is much higher than the external concentration. This indicates that the energy has resulted in a decreased affinity of the carrier for lactose on the inside face of the membrane relative to its affinity on the outside. Instead of using the electron transport system, a transmembrane electrical potential, interior negative, can be generated experimentally by diluting vesicles loaded with a high concentration of potassium ions into a medium of low potassium concentration in the presence of valinomycin. The potassium ions flow out down their concentration gradient, carrying positive charge out of the vesicle and leaving behind an interior negative charge. This negative interior can attract protons into the vesicle through the lactose permease, thereby driving lactose accumulation. Finally, if unenergized vesicles are placed in an unbuffered solution that contains a high concentration of lactose, the lactose will flow into the vesicle, bringing along a proton and thereby causing a measurable decrease in the pH of the medium. All these results provide convincing evidence for the coupled movement of proton and lactose.

Transporters are designed to prevent uncoupled movement of substrate without protons or of protons without substrate. If the latter case occurred, it would result in the operation of an uncoupler and allow the futile dissipation of the pmf. How the binding of a proton affects the affinity or binding of the substrate remains an intriguing and central question. It has been shown that the proton must bind before the lactose. If saturating concentrations of lactose are present on both sides of the membrane, the lactose transporter carries out their very rapid exchange independent of the release or re-binding of the proton. This result indicates that the reorientation of the loaded substrate-binding site from facing the interior to facing the exterior does not require changes in proton binding by LacY. If lactose is present on only one side of the membrane, however, its downhill movement is much slower than in the case of exchange and is strongly influenced by the pH. This result indicates that the bound proton must be released from the carrier to allow the empty carrier to re-orient its substrate binding site to pick up another molecule of lactose. This result is in agreement with the model that the binding of a proton is needed to increase the affinity of the carrier for lactose, and that the low

concentration of protons inside the cell or vesicle is the factor that slows the rate of release of lactose and hence drives lactose accumulation.

The lactose permease has been subjected to extensive genetic and biochemical analysis. Surprisingly few amino acid residues are essential for function, although amino acid substitutions that introduce or affect charged residues in the transmembrane region usually interfere with the stability of the protein or its ability to be stably inserted in the membrane. Models for the folding of the transmembrane segments relative to one another have been proposed from genetic and biophysical assays of regional proximity.

4. Efflux systems

The existence and clinical importance of non-specific drug efflux systems have recently been recognized. An important medical finding was the discovery of an ABC protein that mediates the efflux from cells of non-polar planar molecules, many of which are used in cancer chemotherapy. Overexpression of this protein, called the P-glycoprotein or multidrug resistance protein-1 (MDR-1), is often associated with failure of chemotherapy and recurrence of the disease after a previous round of treatment. This protein is a single polypeptide, but it resembles the periplasmic permeases in having two separate transmembrane domains, each with six membrane-spanning segments followed by a domain with the ABC consensus motifs. It is interesting that a homologous protein in mammalian cells, MDR-2, does not mediate drug efflux but is responsible for the translocation of lipids or their flipping from one side of the membrane to the other. Spontaneous flipping of a lipid across membrane bilayers is extremely slow, and hence an ABC transporter may be assigned this function in cells. Another related protein catalyzes bile acid transport out of liver cells. There are probably many more functions for ABC transporters.

It subsequently has become clear that non-specific efflux systems are widespread in bacteria and account for serious examples of multiple antibiotic resistance. Unlike the ATP-dependence of the MDR carrier, the bacterial efflux systems are coupled to the proton gradient. Most systems possess 4, 12, or 14 transmembrane segments; those with four appear to function as a trimer. In *E. coli*, the major non-specific efflux system is called the Acr system, indicating its initial discovery as a factor that conferred resistance to acriflavins. It comprises three proteins: AcrB, a proton-coupled cytoplasmic membrane transporter; AcrA, a lipoprotein than spans the periplasmic space; and TolC, an outer membrane pore-forming protein. Although not essential for growth, the Acr system can very effectively pump

many amphiphilic or lipophilic molecules from the cytoplasmic membrane through the outer membrane directly into the medium. This systems is just one example of complex transport systems that act across multiple cellular compartments.

5. Phosphotransferase system

Many bacterial species, but not archaea or eukarya, possess sugar uptake systems that carry out the simultaneous transport and phosphorylation of the sugar. The phosphoenolpyruvate:sugar phosphotransferase system (PTS) uses phosphoenolpyruvate (PEP) as phosphate donor, which is transferred successively to two proteins that act in common in all PTS systems. The enzyme I protein transfers phosphate from PEP to HPr, a small protein that is phosphorylated on a histidine residue. HPr serves as phosphate donor to the sugar-specific components, which comprise three protein domains that can be linked together in various orders and combinations. The IIC domain spans the membrane and catalyzes transport of the sugar, but only under conditions in which it is phosphorylated during its passage. The IIA and IIB domains receive phosphate from HPr-P and transfer it to the sugar molecule that is carried by the corresponding IIC domain. This transport mechanism provides a very economical method to combine the phosphorylation that must occur during sugar metabolism with the transport process. Although the PTS allows substrate accumulation, it is not considered active transport because the substrate is modified during transport, and the metabolic energy has been expended in the substrate modification rather than during the transport.

It is interesting that the PTS system plays a major role in the regulation of cellular metabolism, and the transport of PTS sugars inhibits uptake of potential carbon sources through other types of transport systems. Part of this mechanism involves the inhibitory interaction of the IIA component of the glucose PTS with a variety of transporter proteins for other sugars.

C. Export of surface molecules

All bacteria have specialized processes for the secretion or export of proteins and polysaccharides across the cytoplasmic membrane to the periplasm, cell wall, outer membrane, or external medium. Exported components can comprise 10% or more of the weight of the cell, indicating the magnitude and variety of macromolecular transport activities that occur. For peptidoglycan, lipopolysaccharide, and capsular

polysaccharide synthesis, the precursor subunits are translocated across the cytoplasmic membrane and assembled on its outer surface. Some of these precursors are flipped across the membrane after they are coupled to a lipid membrane carrier.

There are several specialized mechanisms for secretion of proteins. To be secreted, a protein must carry a suitable secretion signal. The most common of these is the signal peptide, an amino-terminal extension that is removed during secretion. The typical signal peptides in all cell types comprise 20–30 amino acids with positively charged residues at the amino terminus and then a stretch of hydrophobic residues, followed by a more polar stretch and a peptidase cleavage site. Variants of this structure are used to target proteins to specific cellular organelles in eukaryotic cells. The Sec system acts on the majority of translocated proteins in bacteria. It operates along with several cytoplasmic chaperone proteins, mainly one called SecB, that slow the folding of the precursor protein into its stable final structure, which would prevent its movement across the membrane. The SecYEG protein complex in the cytoplasmic membrane forms a channel through which the polypeptide chain can move. The SecA protein plays a crucial role by binding to the precursor in the cytoplasm, bringing it to the SecYEG translocation complex, and sequentially inserting approximately 30 amino acid segments to the other side of the membrane. The insertion process requires ATP hydrolysis. The SecA and SecB proteins are found only in bacteria and not eukaryotic cells. Once the signal peptide has appeared on the other side of the membrane, it is cleaved off by the action of a leader peptidase enzyme.

Other secretory systems operate in bacteria. The Tat system is named for the twin-arginine motif present in the signal sequences of its substrates, and can move even folded proteins across the cytoplasmic membrane. The SRP-dependent system is related to the process that predominates in eukaryotic cells and involves a signal recognition particle. This system also uses the SecYEG complex for transmembrane movement of its substrate proteins during their synthesis on the ribosome, and appears to be used mainly for proteins destined to the cytoplasmic membrane.

At least five types of transport systems allow export of specific proteins out of the cell. These proteins employ special targeting signals to specify their entry into the appropriate secretory pathway. One of these, the type II secretion system, uses the Sec pathway for initial movement of the precursor into the periplasmic space, where a very complex protein assemblage recognizes the exported protein and moves it across the outer membrane. The type I secretion system resem-

bles the Acr multidrug efflux system in the simplicity and location of its protein components, except that the cytoplasmic membrane component uses the energy of ATP hydrolysis for its action. The type III and type IV secretion systems are of particular interest because they can secrete their substrate proteins, or DNA–protein complexes carried by some type IV systems, directly into a eukaryotic cell. Other specialized systems exist for the assembly of flagella and fimbrial adhesins (pili and fimbriae) on the cell surface. The number, mechanism, and regulation of the many specialized export systems have only recently begun to be understood.

D. Cell growth

1. Cell division

The cytoplasmic membrane plays numerous important roles in the processes of cell growth and division. The rate of growth of a cell is determined by the rates of synthesis of its macromolecules, RNA and protein. Their continued production produces pressure that drives the expansion of the cytoplasmic membrane, with the insertion of additional membrane proteins and of the phospholipids to maintain a set protein:lipid ratio. Somehow, the pressure of the expanding cytoplasm triggers insertion of additional cell wall material to allow the increase in cell volume. Once the cell volume has reached a critical point, or the concentration of a specific protein has reached a certain concentration, or a certain time has passed since the chromosome was replicated, the process of cell division is initiated. A critical step in cell division is the assembly of a ring of tubulin-like FtsZ proteins from the cytoplasm onto the membrane at the division site. This assembled complex contracts to pull the membrane together at the division septum to close off the two progeny cells.

A poorly understood process of cell division that may require membrane action is the separation and equal partitioning of the bacterial chromosomes into each progeny cell. In one model, the chromosomes attach to a membrane protein and are pulled apart by the growth of the membrane. This model is unlikely to account for the rapidity with which chromosome separation can occur under certain conditions, but no convincing evidence for cytoskeletal components that might pull the chromosomes apart has been presented.

2. Signal transduction

Bacterial gene expression is very responsive to changes in the cell's environment, and many types of regulatory

systems allow specific genes to respond to the presence of or need for a wide range of pathway substrates or products. Some regulatory systems are controlled by the binding of the effector molecule to a specific DNA-binding protein that controls the level of expression of the controlled gene. Other systems are controlled by effector molecules that remain outside the cell. Many of these are controlled by two-component regulatory systems, which are widespread in bacteria and archaea and even occur in eukarya. One component of these systems is a transmembrane protein that recognizes its effector molecule in the medium and responds to its binding by a transmembrane signaling event that changes its ability to phosphorylate or to transfer that phosphate. Phosphorylation of the sensor kinase protein can result in transfer of that phosphate to the second component, which is a response regulator protein. The ability of the response regulator protein to bind to a target DNA sequence or to activate transcription of that gene is directly related to the level of its phosphorylation. This mode of transmembrane signaling by regulation of protein phosphorylation is reminiscent of the myriad signaling processes in eukaryotic cells, although the mechanisms and components are not related.

3. Cell movement

Bacteria exhibit several types of motility. Many rod-shaped bacteria and a few cocci can swim through liquid medium through the use of flagella. Flagella are long, helical filaments that extend from the poles or the periphery of the cell body and are assembled from a single protein subunit, called flagellin. Motility is initiated by the rotation of the flagellar filament, which in the case of bacteria with multiple filaments results in their coalescence into a bundle that acts similar to a propeller. Their rotation is driven by the downhill entry of protons through the flagellar basal body, a complex structure embedded in the cytoplasmic membrane and driven by the pmf.

Spirochetes are spiral-shaped bacteria in which the cell body is wrapped around the flagellar filaments which grow from the cell poles. Their flagella do not extend into the medium but are retained in the periplasmic space. These bacteria exhibit a characteristic corkscrew motility that is thought to result from rotation of the endo-flagella.

Several types of bacteria are capable of movement on solid surfaces or in very viscous solutions, in which flagella are ineffective. In some types of these bacteria the mechanism of movement is unknown, whereas in some enteric bacteria, such as *Proteus*, this swarming motility is related to differentiation of the

cell into very long forms that are covered with a profusion of lateral flagellar filaments.

Motility is a regulated process that allows bacteria to swim toward or away from gradients of nutrients or repellents or physical conditions, such as oxygen or light. Response to chemical attractants or repellents is called chemotaxis and this senses whether a bacteria is moving in a direction which increases or decreases the concentrations of the chemical signal. In the absence of a signal, bacteria exhibit periods of swimming in a straight line followed by short periods in which they tumble aimlessly before setting off in a new direction. Straight-line swimming is associated with counterclockwise (CCW) rotation of the flagellum (viewed toward the cell), and tumbling is associated with clockwise (CW) flagellar rotation. The process of chemotaxis controls the direction of rotation so that when cells are swimming in a favorable direction, their period of straight swimming (CCW rotation) is extended. Movement in an unfavorable direction results in an increased frequency of tumbling (CW rotation). This process is controlled by several chemoreceptors in the cytoplasmic membrane, whose occupancy by substrates indicates the level of the chemical signals. Occupancy of these receptors by their ligands results in changes in the activity of a protein kinase that is related to the two-component regulatory systems described previously. Changes in the activity of the kinase result in changes in the level of phosphorylation of a small cytoplasmic protein, CheY, whose phosphorylated form signals CW rotation of the flagella. Another form of covalent modification is the methylation of certain glutamate residues on the chemoreceptors which serves to adjust their signaling properties and allow the receptors to respond to changes in the level of the chemicals rather than to their static concentration. This adaptive response allows the bacterium to resume its normal behavior once it finds itself in a steady supply of the chemical attractant and to prepare to set off in response to new signals. Chemotaxis thus provides a well-studied example of transmembrane signaling and communication between protein complexes in the cytoplasmic membrane. Of particular interest is the localization of the chemoreceptors and associated components at the poles of the cell.

V. ISOLATION OF MEMBRANES

Procedures have been developed for the isolation of cellular membranes from many bacteria. These procedures are modified owing to differences in the composition and content of peptidoglycan cell wall and of

the outer membrane or other surface layers. For the gram-negative *E. coli*, membranes are most reliably isolated following disruption of the cell either by decompression in a French pressure cell or by osmotic lysis following disruption of the peptidoglycan cell wall with the degradative enzyme lysozyme. Cytoplasmic membrane vesicles that are used for transport studies are obtained by osmotic lysis of such spheroplasts (or operation of the French pressure cell at low pressure) and generally have only a somewhat smaller volume than that of the intact cell and are mainly in the right-side-out orientation. Membrane vesicles that are prepared by more vigorous cell disruption by sonication or operation of the French pressure cell at high operating pressure tend to be much smaller in volume and in the inside-out or everted orientation.

After unbroken cells are removed by low-speed centrifugation, the total membrane fraction can be collected by ultracentrifugation. Sucrose density gradient centrifugation can be used for removal of ribosomes, peptidoglycan fragments, and other large complexes and for separation of the cytoplasmic and outer membranes. Because of its content of lipopolysaccharide, the density of the outer membrane in *E. coli* is higher than that of the cytoplasmic membrane. In other gram-negative bacteria, the densities of the two membranes are similar, and their separation by this technique is not as effective.

An alternative approach for separation of the proteins from the cytoplasmic and outer membranes in enteric bacteria takes advantage of the resistance of most outer membrane proteins to solubilization by nonionic detergents in the presence of divalent cations. This rapid method cannot be relied on for localization of all membrane proteins since it has been tested only on a limited set of proteins and depends on features that are not necessarily universally maintained. Detergents are amphipathic molecules that are able to associate with and disrupt membrane structure. They allow the lipids to form a spherical micellar structure and provide the membrane proteins with a suitable environment for their non-polar surfaces in molecular aggregates much smaller than the membrane. Many nonionic detergents allow membrane proteins to retain their structure and function.

VI. MEMBRANE ASSEMBLY AND CONTROL OF COMPOSITION

The process of membrane assembly is becoming increasingly understood. Insertion of integral proteins

into the cytoplasmic membrane is determined by the presence of hydrophobic or amphiphilic stretches of amino acid residues that represent potential transmembrane segments. Most cytoplasmic membrane proteins do not have a cleaved signal sequence that directs them to the membrane. The exceptions are proteins which are anchored in the membrane but are mainly exposed to the outside; these undergo processing and removal of a signal sequence. The orientation of the transmembrane segments of an integral membrane protein is determined primarily by the pattern of charged amino acid residues on the two polar loops on either side of the segment, which generally obey the positive-inside behavior. Although most integral membranes can insert spontaneously into lipid bilayers, their insertion in the cell appears to be facilitated by cytoplasmic chaperones and the Ffh and FtsY proteins that are related to the components of the eukaryotic signal recognition system, SRP. The components of the Sec system do not seem to be necessary, unless the protein contains a large (160 residues) external segment.

Membrane phospholipids are made by cytoplasmic and membrane-associated enzyme pathways. New phospholipids are inserted into the inner face of the cytoplasmic membrane and must flip across to the outer leaflet. This flipping process is extremely slow without the involvement of a protein catalyst. There is a considerable degree of membrane asymmetry in membranes of eukaryotic cells, with a substantially different lipid composition in the two leaflets of the bilayer. Such asymmetry appears less prominent in bacterial membranes but has not been studied in detail.

The lipid composition of cellular membranes changes in response to environmental conditions and growth state. Lower growth temperatures result in the incorporation of fatty acids with a higher degree of unsaturation than those that are present at higher growth temperatures so as to maintain a sufficient level of membrane fluidity. This sensing and response to ambient temperature involves selective synthesis and incorporation of different fatty acids by the appropriate enzymes of lipid biosynthesis rather than changes in levels of these enzymes. When cells of *E. coli* enter the stationary phase of growth, an enzyme is produced that adds a methyl group across double bonds in fatty acids to convert unsaturated fatty acids to the corresponding cyclopropane fatty acids. These cyclopropane fatty acids have similar effects on membrane dynamics as those with double bonds but are more stable to oxidative damage.

Phospholipid head groups determine certain properties of the membrane. The acidic phospholipids in

E. coli, PE and cardiolipin, are necessary for the incorporation and function of many membrane enzymes and transporters. Anionic phospholipids are essential for stimulating the ATPase activity of the SecA protein during its translocation of proteins across the membrane. These lipids are also necessary for the activation of ATP binding to the DnaA protein, which plays the central role in the initiation of bacterial chromosome replication. The use of mutants defective in the various lipid biosynthetic pathways revealed that a minimal quantity of acidic phospholipids was essential for cell growth, although cardiolipin was dispensable. The other major lipid, PE, is noted for its ability to form non-lamellar structures under certain conditions. Mutants that are completely blocked in the synthesis of PE can grow, but only in the presence of elevated concentrations of divalent cations, which promote non-lamellar structures in cardiolipin. In this mutant, cardiolipin synthesis is essential for growth. It is thus clear that the membrane can tolerate a wide range in the lipid head group composition, as long as there is a minimal level of acidic phospholipids and of lipids that can form nonlamellar structures. It has proven difficult to determine the effect of changes in lipid composition on individual membrane functions in the intact cell because of the activation of a stress response system under these conditions. The fluid state of the membrane certainly affects the activity of numerous membrane proteins, indicating that acyl chain or lipid mobility are necessary for their proper function or insertion. One expects substantial progress in the future in understanding the structures and interactions of lipids and proteins in the cytoplasmic membrane.

Cell Walls, Bacterial

Joachim-Volker Höltje

Max-Planck-Institut für Entwicklungsbiologie

GLOSSARY

autolysins Endogenous murein hydrolases, which cleave bonds in the peptidoglycan sacculus that are critical for the mechanical strength of the structure and thus cause lysis (autolysis) of the bacterium.

cell envelope A multilayered structure that engulfs the cytoplasm. The innermost layer, the cytoplasmic membrane, is stabilized by an exoskeleton of peptidoglycan (murein). Gram-negative bacteria have a second lipid bilayer, called the outer membrane, making the envelope of gram-negative bacteria less permeable compared to that of gram-positive bacteria.

Gram stain Iodine–gentian violet complex that is retained by some bacteria (called gram-positive) but is released from the envelope by acetone or ethanol from another group of bacteria (called gram-negative). Whereas gram-positive bacteria have a multilayered shell of peptidoglycan, gram-negative bacteria have a thin (monolayered) peptidoglycan and a second membrane, the outer membrane.

lipoproteins Proteins carrying at their amino terminus a cysteine to which glycerol is linked that has its hydroxyl groups substituted by fatty acids. In addition, the amino group of Cys is also modified by a fatty acid. A murein lipoprotein is covalently attached to the cell wall of gram-negative bacteria with its carboxyl terminus and at the same time is inserted with its lipophilic amino terminus into the

outer membrane, thereby connecting murein and the outer membrane.

lysozyme β -1,4-*N*-acetylmuramidase that hydrolyses the β -1,4 glycosidic bond between *N*-acetylmuramic acid and *N*-acetylglucosamine in peptidoglycan. It is found in many bacteria, where it is involved in the growth processes of the cell wall. It is also present in various tissues and secretions of higher organisms (e.g. hen egg white lysozyme), where it functions as a powerful antibacterial agent.

murein Synonym for peptidoglycan, a cross-linked biopolymer of poly-(*N*-acetylglucosamine- β -1,4-*N*-acetylmuramic acid) that is cross-linked by peptide bridges that are linked to the lactyl group of the muramic acid residues (from *Murus*, a Latin word meaning wall).

murein sacculus The bacterial exoskeleton that forms a bag-shaped macromolecule completely enclosing the cell. It endows the cell with mechanical strength and confers the specific shape to the bacterium.

penicillin-binding proteins Enzymes that covalently interact with penicillin by forming a penicilloyl–enzyme complex. The family of penicillin-binding proteins consists of bifunctional transglycosylase-DD-transpeptidases, DD-transpeptidases, DD-endopeptidases, and DD-carboxypeptidases.

periplasm A specific cellular compartment of the cell envelope of gram-negative bacteria confined by the cytoplasmic membrane and the outer membrane.

teichoic acid Anionic polyol-phosphate polymer covalently bound to the muramic acid of peptidoglycan in gram-positive bacteria. Ribitol- and glycerol teichoic acids are known.

The **Bacterial Cell Envelope** is a complex structure consisting of different layers that have to fulfill many critical functions for the cell. Besides being a protective shield against the hostile environment, it must allow communication with the surroundings in order for the bacteria to find optimal conditions for growth. This highly developed cell organelle has to be mechanically stabilized to withstand the high intracellular osmotic pressure of approximately 2–25 atm. Eubacteria as a rule reinforce their cell envelope by an exoskeleton made of peptidoglycan (murein), a cross-linked biopolymer that is extremely well suited to endow the cell with sufficient strength. In order to achieve this, the murein forms a closed bag-shaped structure, called sacculus, completely wrapping up the cell. Importantly, the murein sacculus not only stabilizes the cytoplasmic membrane but also maintains the specific shape of the bacterium. Morphogenesis of bacteria can therefore be studied by analyzing the metabolism of a single macromolecule—the murein sacculus.

I. CELL ENVELOPE STRUCTURE

On the basis of a special staining procedure bacteria can be subdivided in essentially two groups, the gram-positive and the gram-negative bacteria. Interestingly, this reflects a fundamental difference in the general construction of the cell envelope (Figs 19.1 and 19.2). The staining method by Christian Gram consists of two steps. First, the heat-fixed cells are stained with a dark-blue iodine gentian violet dye complex. In the second step, the cells are extracted with ethanol. If the cells are destained during this step they are referred to as gram-negative bacteria, and if the stain remains within the cell envelope the bacteria are called gram-positive.

A typical gram-positive envelope consists of a cytoplasmic membrane and a thick, multilayered murein shell (20–50 nm thick) which is decorated by teichoic acids (Fig. 19.2). The gram-negative bacterium is enclosed by two bilayers, a cytoplasmic membrane and an outer membrane confining a unique compartment called the periplasmic space (Fig. 19.2). The murein sacculus of gram-negative bacteria is embedded into this space and is characteristically extremely thin, forming only one continuous layer (approximately 3 nm thick). The outer membrane and the murein layer are connected by a lipoprotein that has

FIGURE 19.1 Electron micrographs of negatively stained sections of bacterial cell walls. (Top) Gram-negative bacterium *Escherichia coli*; (bottom) gram-positive bacterium *Staphylococcus aureus*. P, periplasmic space; OM, outer membrane; PG, peptidoglycan; CM, cytoplasmic membrane. Scale bar = 0.1 μ m (courtesy of Drs. H. Frank and H. Schwarz).

its fatty acid-substituted amino terminus immersed in the outer membrane and its carboxyl terminus covalently linked to the murein (Figs 19.2 and 19.4). Unlike the cytoplasmic membrane, the outer membrane is a highly asymmetric lipid bilayer structure with an inner leaflet consisting of phospholipids and an outer leaflet of lipopolysaccharides. Typically, the outer membrane contains pore-forming proteins, known as porins.

The most important structural distinction between gram-positive and gram-negative bacteria is the presence in the latter group of a second bilayer system, the outer membrane. Due to this additional permeability barrier, gram-negative bacteria show significantly higher minimal inhibitory concentration values for many antibiotics than do gram-positive bacteria. As a consequence, some otherwise quite powerful antibiotics are of no therapeutic use for the treatment of gram-negative infections. Besides a general hindrance to the uptake of hydrophilic compounds, the existence of a second permeability barrier has many additional consequences for cell wall metabolism. It allows the cell to reduce the thickness of its murein to just one single layer and makes it possible to efficiently recycle the valuable murein turnover products that accumulate during growth in the periplasmic space.

GRAM-negative

GRAM-positive

II. CHEMISTRY OF BACTERIAL CELL WALLS

The structural principle that glycan strands are cross-linked by peptides in order to form a strong lattice-work for a bacterial exoskeleton has been invented in nature twice, in Archaea and in Eubacteria. Archaea contain a compound called pseudomurein. Although the architectural style is the same in pseudomurein and in murein, the building materials are different.

A. Peptidoglycan (murein)

The murein of Eubacteria consists of glycan strands that are cross-linked by peptides (Figs 19.3 and 19.7). The amino sugars *N*-acetylglucosamine (GlcNAc) and *N*-acetylmuramic acid (MurNAc) are polymerized by β -1,4 glycosidic bonds in an alternating order; thus, the glycans have one GlcNAc and one MurNAc terminus. The latter represents the reducing end of the polysaccharide. In some species the terminal MurNAc residue is modified to a non-reducing 1,6-anhydromuramic acid (Fig. 19.3). The lactyl group of the muramic acid is substituted by a short peptide consisting of L- and D-amino acids in an alternating sequence. The presence of LD and DD peptide bonds renders the peptides resistant to the majority of peptidases. Cross-linkage of two peptides is made possible by the presence of a diamino acid, such as L-lysine, *meso*-diaminopimelic acid, or L-ornithine. This allows the formation of a tail to tail bridging peptide bond between the terminal carboxyl group of a D-Ala in position 4 of one peptide moiety

and the non-alpha amino group of the diamino acid at position 3 of another peptide side chain (Figs 19.3 and 19.7). In many gram-positive bacteria the cross-linkage is not a direct one but is mediated by an additional peptide called "Intervening peptide." A pentaglycine, for example, is inserted between the D-Ala and the L-Lys in the case of *Staphylococcus aureus*. In contrast to the types of cross-linkages referred to as group A, in which the cross-linkage is between positions 4 and 3 of two peptides, the linkage in group B is via an intervening peptide containing one diamino acid that allows for a cross-linkage between the alpha-carboxyl group of the D-Glu in position 2 of one peptide to the carboxyl group of D-Ala in position 4 of another peptide (Fig. 19.3). In general there are only a few modifications of the sugar part. The glycans can be O₆-acetylated, which makes the murein resistant towards the action of hen egg white lysozyme, or they can be de-N-acetylated, as is the case in *Bacillus cereus*.

B. Murein lipoprotein

The murein of gram-negative bacteria is substituted by a lipoprotein that on average is attached to every tenth muramic acid residue. The linkage is from the epsilon amino group of the lysine at the carboxyl terminus to the carboxyl group at the L-center of *meso*-diaminopimelic acid (Fig. 19.4). The murein lipoprotein is a member of the superfamily of lipoproteins that are characterized by a typical consensus processing site (LLLAGCSSNS). The unmodified prolipoprotein that carries a typical amino-terminal leader is exported to

FIGURE 19.4 Biosynthetic pathway of the murein lipoprotein. R₁-R₃ indicate fatty acids with a composition similar to that of the phospholipids of the bacterium.

the periplasmic side of the cytoplasmic membrane where the SH group of the Cys is substituted by glycerol (Fig. 19.4). Two fatty acids are added to the hydroxyl groups of the glycerol moiety to yield the diglyceride prolipoprotein. A specific signal peptidase (signal peptidase II) cleaves the leader, releasing the amino group of the Cys to which a third fatty acid is linked. The free form of the mature lipoprotein is hooked to the murein by an unknown adding enzyme. Globomycin specifically inhibits the signal peptidase II.

The function of the lipoprotein is probably to connect the outer membrane with the murein sacculus (Fig. 19.2). Although mutants in *Lpp* are viable, they often show blebs of outer membrane vesicles at the site of cell division where all three layers of the envelope, the outer membrane, the murein, and the cytoplasmic membrane have to be contracted simultaneously. When the *Lpp* mutation is combined with a defect in

the major outer membrane protein *OmpA*, *Escherichia coli* can no longer maintain its rod shape and grows as spheres, but only when sufficient Mg²⁺ is added.

C. Teichoic acid

An anionic polyol-phosphate polymer, called teichoic acid, constitutes the outermost part of the peptidoglycan shell of gram-positive bacteria. The polyol can be either ribitol or glycerol. Most glycerol teichoic acids are 1,3-linked. Many substitutions, such as D-alanine, L-serine, glycine, glucose, and GlcNAc can occur. Teichoic acids are linked via a special linkage unit by a phosphodiester to the C₆ of the muramic acid. Because of the equally spaced phosphate groups, teichoic acids strongly bind magnesium ions. It has been speculated that teichoic acids function as a kind of ion exchanger. Thus, the teichoic acid layer forms a type of cell compartment that may have a function similar to that of the periplasmic space of gram-negative bacteria.

Upon transfer to phosphate-limiting growth conditions, teichoic acid synthesis rapidly decreases and synthesis of a teichuronic acid takes over. Unlike teichoic acids, teichuronic acids lack the phosphate group in the repeating units. The teichuronic acid of *Micrococcus luteus* is formed from the disaccharide D-N-acetylmannosaminuronic acid-β-1,6-D-glucose that is polymerized by α-1,4-glycosidic bonds up to 10–40 mers. The teichuronic acid of *Bacillus licheniformis* consists of equimolar amounts of N-acetylgalactosamine and D-glucuronic acid.

D. Pseudomurein

Pseudomurein resembles murein in that it has the same structural engineering as murein. However, the glycan strands consist of GlcNAc or N-acetylgalactosamine and N-acetylglucosaminuronic acid, linked together by β-1,3 glycosidic bonds. The peptide bridges that are hooked to the carboxyl group of the talosaminuronic acid contain L-amino acids, including Lys, Glu, Ala, Thr, and Ser. As a consequence of this different chemical setup, the synthesis of pseudomurein is not inhibited by D-cyloserine, vancomycin, or penicillin, which are typical inhibitors of murein synthesis.

III. BIOSYNTHESIS OF PEPTIDOGLYCAN (MUREIN)

A. Cytoplasmic reaction steps

The biosynthetic pathway of the murein sacculus involves three cellular compartments: synthesis of

FIGURE 19.5 Biosynthetic pathway of the murein precursor UDP-*N*-acetylmuramyl pentapeptide.

soluble murein precursors in the cytoplasm (Fig. 19.5), transport of the lipid-linked murein precursors across the cytoplasmic membrane (Fig. 19.6), and insertion of the precursors into the pre-existing murein sacculus in the extracellular space or, in the case of gram-negative bacteria, in the periplasmic space (Figs 19.6 and 19.7).

The first biosynthetic intermediate that is specific for murein is UDP-*N*-acetylmuramic acid (UDP-MurNAc). It is formed by a transfer of enolpyruvate from phosphoenolpyruvate to UDP-*N*-acetylglucosamine (UDP-GlcNAc), followed by NADPH catalyzed reduction of the intermediate UDP-GlcNAc-enolpyruvate to the lactate-substituted glucosamine known as muramic acid (Fig. 19.5). The antibiotic fosfomycin (phosphonomycin, *L*-*cis*-1,2-enolpropylphosphoric acid) is a potent inhibitor of the UDP-GlcNAc-enolpyruvyl transferase. The lactate moiety of muramic acid functions as an acceptor for the first amino acid of the pentapeptide side chain. The additional amino acids are added sequentially by specific synthases that couple the cleavage of ATP to the formation of a peptide bond. The

correct sequence of the pentapeptide, an alternating succession of *L*- and *D*-amino acids, is determined by the substrate specificity of the synthases. However, the *L*-alanine adding enzyme also accepts *L*-serine and glycine and the *meso*-diaminopimelic acid adding enzyme from *E. coli* also accepts the sulfur-containing diaminopimelic acid analog, lanthionine. Interestingly, the last two amino acids, both of which are *D*-alanine, are added in the form of the *D*-alanyl-*D*-alanine dipeptide pre-synthesized by a *D*-alanine ligase. The *D*-Ala-*D*-Ala adding enzyme completes the synthesis of the UDP-MurNAc-pentapeptide precursor. Other *DD*-dipeptides in addition to *D*-Ala-*D*-Ala can be added by the ligase; in particular, glycine and *D*-lactate can substitute for one of the *D*-Ala residues. Both the *L*-alanine racemase and the *D*-alanine racemase are inhibited by *D*-cycloserine and related compounds such as *O*-carbamoyl-*D*-serine, haloalanines, and alaphosphin (*L*-alanyl-*L*-1-aminoethyl phosphonic acid).

B. Membrane translocation of murein precursors

For insertion into the murein sacculus the activated precursors UDP-GlcNAc and UDP-MurNAc-pentapeptide must be transported across the cytoplasmic membrane (Fig. 19.6). The details of this important step are poorly understood. An undecaprenylphosphate (C_{55} -isoprenoid) molecule, also called bactoprenol, functions as a vehicle (lipid carrier) to shuffle the hydrophilic precursors from the inner to the outer side of the cytoplasmic membrane. A translocase, phospho-*N*-acetylmuramyl pentapeptide translocase (*MraY*), transfers the phosphoryl-muramyl pentapeptide to undecaprenylphosphate to yield the so-called lipid intermediate I, undecaprenyl-diphosphoryl-*N*-acetylmuramyl pentapeptide. The translocase reaction is fully reversible and is inhibited by tunicamycin. This enzyme also catalyzes an exchange reaction between UMP and UDP-MurNAc pentapeptide. In a second step, catalyzed by the transferase *N*-acetylglucosamine transferase (*MurG*), GlcNAc is transferred from UDP-GlcNAc to lipid I to form the final murein precursor undecaprenyl-diphosphoryl-*N*-acetylmuramyl(pentapeptide)-*N*-acetylglucosamine, also called lipid intermediate II. Both translocase and transferase are bound to the inner side of the cytoplasmic membrane thus, the final murein precursor accumulates at the inner side of the membrane to which it is anchored via the undecaprenylphosphate moiety. To be available for insertion into the murein sacculus, the lipid-linked precursor has to be translocated across the cytoplasmic membrane. The antibiotic

vancomycin forms complexes with the D-Ala-D-Ala terminus of the precursor and this blocks murein synthesis. It is unlikely that a spontaneous flip-flop of the lipid intermediate II would be fast enough to match the rate of murein. Therefore, it is expected that the process is facilitated by auxiliary proteins.

C. Insertion of murein precursors into the wall

The murein disaccharide pentapeptide is inserted into the existing murein net by the formation of glycosidic and peptide bonds (Fig. 19.7). A transglycosylase first catalyzes the cleavage of the phosphodiester bond by which a nascent glycan strand is still linked to the undecaprenyl pyrophosphate and then catalyzes the transfer of the glycan strand onto the C₄ hydroxyl group of the GlcNAc residue of a lipid-linked disaccharide pentapeptide precursor. The glycolipid antibiotic moenomycin specifically inhibits the transglycosylation reaction. The released bactoprenol pyrophosphate is then processed to bactoprenol monophosphate in order to be accepted again by the translocase (Fig. 19.6). Bacitracin, an antibiotic that

binds strongly to the bactoprenol pyrophosphate, inhibits the recycling of the lipid carrier. The formation of the cross-linkage of the peptide side chains to acceptor peptide side chains in the sacculus is catalyzed by a transpeptidase. Like transglycosylation, transpeptidation is also a two-step transferase reaction. First, the terminal D-Ala-D-Ala peptide bond of the pentapeptide precursor is cleaved, the terminal D-Ala is released, and a substrate-enzyme intermediate is formed. In a second reaction step the murein peptidyl moiety is transferred to a free amino group on an acceptor peptide side chain. As a consequence of transglycosylation and transpeptidation, the precursors are polymerized in two directions yielding the characteristic net structure of murein. Interestingly, in some bacteria, bifunctional enzymes combining a transglycosylase domain with a transpeptidase domain are responsible for the polymerization of the murein precursors.

Penicillin inhibits murein transpeptidases because of its analogy to the D-alanyl-D-alanine terminus of the murein precursor (Fig. 19.8a). The inhibition depends on the enzymatic interaction of the enzyme with the antibiotic. In analogy to the cleavage of the D-Ala-D-Ala bond (Fig. 19.7), the β -lactam ring is cleaved by the

FIGURE 19.8 (A) Structural analogy between penicillin and D-alanyl-D-alanine. The arrows indicate the bonds cleaved by penicillin-sensitive DD-transpeptidases, DD-endopeptidases, and DD-carboxypeptidases. (B) Formation of the penicilloyl-enzyme intermediate.

enzyme and a covalent substrate (penicilloyl)-enzyme intermediate is formed that involves a Ser in the catalytic site (Fig. 19.8b). This intermediate is inert and does not react further. Thus, the enzyme is blocked by the covalently linked penicillin molecule, which may be considered a "suicide substrate" for the transpeptidases. Not only the DD-transpeptidases but also other enzymes specifically recognizing D-D peptide bonds, including DD-carboxypeptidases and DD-endopeptidases, are penicillin-sensitive enzymes. These proteins are collectively referred to as penicillin-binding proteins (PBPs). Since inhibition of the PBPs by penicillin is due to the formation of a covalent enzyme-penicillin intermediate (Fig. 19.8), a simple assay allows the identification of all PBPs of a given strain. Incubation of whole cells or cell fractions with a labeled (e.g. radioactively) penicillin followed by sodium dodecyl sulfate (SDS)-polyacrylamide gel electrophoresis results in a species-specific PBP pattern.

IV. ARCHITECTURE OF THE MUREIN SACCULUS

A. Structure of murein sacculi

The cell wall can be isolated in the shape of the intact murein sacculus by boiling cells in 4% SDS. When inspected by electron microscopy the final sacculi preparation shows empty bag-shaped structures that reflect the shape of the cells from which they have been isolated. The murein structure (i.e. its composition of muropeptide subunits) can be analyzed by a complete hydrolysis of isolated murein sacculi using a muramidase, followed by separation of the products by reversed-phase high-pressure liquid chromatography.

Stereochemical calculations and X-ray diffraction data indicate that the disaccharide units in the strands are twisted in relation to one another, forming a four- to five-fold helix structure. As a result, the peptide moieties protrude alternately upwards, to the left, downwards, right, and so forth. This arrangement allows a strand to be cross-linked to both neighboring strands in one layer and strands in an upper and lower level, thus forming a perfect three-dimensional framework. The average length of the glycan strands can be calculated when the total number of disaccharide subunits and the number of reducing ends are known. For gram-positive bacteria, lengths between 40 and 80 units have been observed. The average length of the glycan strands in the gram-negative *E. coli* was found to be approximately 21 disaccharide units. For *E. coli*, the length distribution could be determined by separating the glycan strands that were released from the sacculus by

amidase treatment. The majority (70%) of the glycans were found to be short, with a length of approximately seven to nine disaccharide units.

The orientation of the glycan strands in the murein sacculus is still a matter of debate. In the case of rod-shaped bacteria, the glycan strands could either be running along the shorter circumference or arranged parallel to the long axis of the cell. A rhombic, "Chinese finger puzzle-like pattern" can also be envisaged, and even a completely unordered structure cannot be discounted. Despite the lack of clear-cut experimental data, it is tempting to speculate that some kind of order must exist in order to facilitate (assist) the ordered growth of the shape-maintaining structure of the bacterium.

The murein structure is endowed with a great degree of flexibility. In particular, the peptide bridges can be stretched by a factor of four. By contrast, the glycan strands are quite stiff and show almost no elasticity. As a consequence, the sacculus can increase in surface when under stress and shrink when relaxing, as is the case for isolated murein sacculi.

B. Barrier function of murein

Because of the latticework of murein the sacculus represents a molecular sieve for larger compounds. The smallest mesh, also called a tessera, in a systematically constructed murein latticework would have a length of a peptide bridge and a width of approximately four disaccharide units. Thus, in the case of *E. coli* it measures approximately $1-4 \times 4-5$ nm. The meshes in the net may not just form rectangles; due to the tension in the wall, they may be stretched into a honeycomb-like hexagon. The exclusion limit for the passage of molecules across the net has been determined *in vitro* to be approximately 50-60 kDa and to be almost the same for the multilayered murein of gram-positive and the thin murein of gram-negative bacteria. For bulky proteins with greater mass, murein is an effective barrier and therefore a localized opening of the murein net is a prerequisite for such molecules to pass through the sacculus. Consequently, the participation of specific murein hydrolases has been proposed for processes such as the export of bulky proteins (i.e. pili and flagellar assembly) and transfer of DNA during conjugation.

V. BACTERIAL CELL WALL GROWTH

A. Cell wall metabolizing enzymes

The vast number of enzymes involved in murein metabolism reflects the complexity and importance of

growth of the cell wall in bacteria. Different and distinct processes are involved. First, the biosynthetic pathway leads to the formation of activated murein precursor molecules. Second, the precursors are inserted into the preexisting murein sacculus. Due to the lattice structure of murein, a concerted action of murein hydrolases and synthases is needed in order to enlarge the surface of the sacculus. Depending on the mechanism employed, many bacteria release surprisingly large quantities of turnover products during growth (see Section III.D). Therefore, a third set of enzymes are specifically involved in degrading and trimming these valuable murein turnover products into structures suitable for recycling for *de novo* murein synthesis. Further complexity is added by the performance of two fundamental processes during growth of the bacterial cell wall: the general expansion of the surface (in the case of rod-shaped bacteria elongation of the cylindrical middle part) and subsequent formation of the septum (see Section V.B). Different enzyme systems seem to be responsible for these two processes. Due to the importance of the perfect execution of cell wall growth and division for cell viability, regulatory enzymes, backup enzymes, and repair enzymes are likely to be involved.

Specific enzymes exist that can cleave all covalent bonds in murein (indicated in Fig. 19.7). Glycosylases have only two specificities. *N*-acetylglucosaminidases cleave the β -1,-4 glycosidic bond between GlcNAc and MurNAc. Muramidases (lysozymes) split the β -1,-4 glycosidic bond between MurNAc and GlcNAc. A unique type of muramidase, called lytic transglycosylase, combines the cleavage of the glycosidic bond with a concomitant formation of a 1-6-anhydro ring at the muramic acid residue (see Fig. 19.3).

Because so many different peptide bonds are present in murein, the number of peptidases is correspondingly high. *N*-acetylmuramyl-L-alanine amidases cleave the amide bond between the lactyl group of the MurNAc and the L-Ala of the peptide side chain. DD-Endopeptidases specifically hydrolyze the bridging peptide bond between the D-Ala of one peptide and the D-center of the dibasic amino acid of another peptide. Whereas DD-endopeptidases are penicillin sensitive (see Section III.C), LD-endopeptidases that specifically hydrolyze the LD-peptide bonds are not inhibited by most β -lactams. DD-Carboxypeptidases remove the terminal D-Ala residue from pentapeptides and LD-carboxypeptidases split off the D-Ala residue in position 4. DD-Carboxypeptidases are sensitive towards β -lactam antibiotics however, LD-carboxypeptidases are inhibited only by β -lactams that carry a D-amino acid in their side chains, such as nocardicin A and cephalosprin C.

With the exception of the carboxypeptidases, murein hydrolases that cleave bonds in the murein sacculus are potentially autolytic enzymes and are thus also referred to as autolysins. Although potentially suicidal, these enzymes are essential for growth. Cleavage of bonds in the pre-existing murein net by hydrolases that allows the insertion of new subunits is a prerequisite for the enlargement of the latticework. In addition, cell separation depends on the splitting of the murein septum by murein hydrolases. It is this group of autolysins that is responsible for antibiotic-induced bacteriolysis. The mechanisms that control the murein hydrolases are not fully understood.

B. Growth and division of the murein sacculus

Growth and division of the murein sacculus are a risky enterprise since the stress-bearing structure that is essential for the cell's integrity has to be enlarged and split into two daughter sacculi. These operations have to be executed while maintaining both the mechanical strength of the wall and the specific shape of the cell. Whereas shape maintenance remains poorly understood, the mechanical stability of the wall during growth is thought to be preserved by a mechanism that enlarges the sacculus by an inside-to-outside growth mechanism (see animation in <http://www.eb.tuebingen.mpg.de/papers/hoeltje/>). Accordingly, new material is first hooked in a relaxed state underneath the existing stress-bearing layers of the wall and, in a second step, is exposed to stress by the cleavage of critical bonds in the old material; this is a strategy called "make-before-break." This mechanism may even result in the release of old material from the sacculus, a phenomenon known as murein turnover. Growth of the thin, mostly monolayered murein of gram-negative bacteria is a far more delicate process. Therefore, it very likely also follows the safe make-before-break strategy. One model proposes that first a murein triplet (i.e. three cross-linked glycan strands) is covalently attached to the cross bridges on both sides of a so-called docking strand of the murein layer under tension. Specific removal of the docking strand by the action of murein hydrolases provokes insertion of the murein triplet into the stress-bearing sacculus.

Growth of spherical bacteria (i.e. cocci) occurs exclusively at the equator of the cell, the future site of cell division (Fig. 19.9). The role of the FtsZ protein in placing the division site at the midpoint of the cell is discussed elsewhere. New material is added in a sharp growth zone to the leading edge of the nascent cross wall. Splitting and peeling apart of the newly

FIGURE 19.9 Schematic representation of the growth modus of cocci. The encircled area of a dividing coccus (top) is shown in detail (bottom). The large, solid arrowhead indicates the addition of new material at the leading edge of the septum. The group of three small arrowheads marks the site of action of the murein hydrolases that split the newly added material. As a result, the material is pushed outwards, thereby increasing the surface of the two daughter hemispheres. The two open arrowheads point to the thickening process of the newly formed peripheral wall. Arrows indicate the two processes of peripheral wall enlarging and centripetal cross-wall extension. Old peptidoglycan is shown in black, newly synthesized material in gray, and the murein added during the thickening process in light gray (modified from Higgins and Shockman, 1976).

added murein results in the material being pushed outwards, thereby causing an increase in the surface of the coccus. The newly synthesized wall is then strengthened by the attachment of additional murein (thickening). Inhibition of the splitting process blocks further pushing outwards of the added material but triggers annularly closing of the cross wall. On completion of the cross wall, a precise cutting of the septum that may involve murosomes (lytic enzymes wrapped into vesicles) allows for cell separation. Murein turnover appears not to occur in gram-positive cocci.

In rod-shaped bacteria the sites of wall growth alternate during the cell cycle (Fig. 19.10). First, the sacculus is elongated while strictly maintaining the diameter. This process occurs as a result of incorporation of new material all over the cylindrical part of the wall, with the poles being metabolically silent. The growth mechanism is also different from that of cocci because it gives rise to an enormous amount of murein turnover. Almost 50% of the murein is released from the sacculus per generation. In the case

FIGURE 19.10 Schematic representation of the growth modus of rod-shaped bacteria. Solid circles represent the random insertion of new material into the cylindrical part of the cell during cell elongation. Note that the diameter of the cell does not change. Open circles represent incorporation of new material in a zonal growth zone at the site of cell division. As a result, the new polar caps formed after cell division are exclusively made of murein synthesized in the growth zone.

of gram-positive bacteria the material newly added to the cylindrical part of the rod is passed on step by step from the inner layers to the outermost layers from where it is finally removed by murein hydrolases. In the case of gram-negative bacteria, it may be the release of the docking strands that is responsible for murein turnover. Septum formation involves a switch to localized incorporation of new material at the equator of the cell, which is defined by the FtsZ protein that forms a ring structure at the site of cell division.

Chemotaxis

Jeff Stock and Sandra Da Re

Princeton University

GLOSSARY

adaptation The return to a preset behavioral state following a response to an altered environmental condition.

attractant A chemical that causes a positive chemotaxis response.

excitation A behavioral response.

information A significant perturbation in a signal transduction system.

intelligence The ability to respond successfully to a new situation.

learning The acquisition of altered sensibilities from previous experience.

memory An internal record of past experience.

receptor A protein that specifically interacts with a particular stimulus to generate a signal that leads to a cellular response.

repellent A chemical that causes a negative chemotaxis response.

sensing The acquisition of information.

Chemotaxis in microbiology refers to the migration of cells toward attractant chemicals or away from repellents. Virtually every motile organism exhibits some type of chemotaxis. The chemotaxis responses of eukaryotic microorganisms proceed by mechanisms that are shared by all cells in the eukaryotic kingdom and generally involve the regulation of microtubule- and/or microfilament-based cytoskeletal elements. In this article, we will be concerned only with bacterial chemotaxis.

All bacteria share a conserved set of just six different regulatory proteins that serve to direct cell motion toward favorable environmental conditions. The same regulatory system operates irrespective of whether motility involves one or several flagella, or whether it occurs by a mechanism such as gliding motility that does not involve flagella. The same basic system mediates responses to a wide range of different chemicals including nutrients such as amino acids, peptides, and sugars (which are usually attractants) and toxic compounds such as phenol and acid (generally repellents). The same proteins also mediate responses to oxygen (aerotaxis), temperature (thermotaxis), osmotic pressure (osmotaxis), and light (phototaxis). As a bacterium moves it continuously monitors a spectrum of sensory inputs and uses this information to direct motion toward conditions that are optimal for growth and survival. To accomplish this task, the chemotaxis system has developed molecular correlates of processes such as memory and learning that are widely associated with sensory motor regulation by higher neural systems.

I. RESPONSE STRATEGY

A. Biased random walk

In a constant environment, motile bacteria generally move in a random walk of straight runs punctuated by brief periods of reversal that serve to randomize the direction of the next run. The chemotaxis system

functions by controlling the probability of a reversal. If, during a run, the system determines that conditions are improving, then it sends a signal to the motor that suppresses reversals so that the cell tends to keep moving in the preferred direction. If, on the other hand, the system determines that conditions are getting worse, then it sends a signal for the motor to change direction. The effect is to bias the random walk so that cells tend to migrate toward attractants and away from repellents (Fig. 20.1). Thus, bacterial chemotaxis is effected by the simple strategy of using environmental cues to modulate the probability of random changes in direction. By using this mechanism, individual cells never have to determine in which direction they want to move. Instead, they simply determine whether they want to continue on course or change direction. The biased random walk strategy is essential to bacterial chemotaxis because it provides a mechanism whereby bacteria can direct their motion despite the fact that bacterial cells are far too small to have a sense of direction.

B. Temporal sensing and memory

Bacterial cells are generally only a few micrometers long. This is too small to possibly measure differences in attractant or repellent concentration over the length of their bodies. In the early 1970s, through the work of Macnab, Koshland, Berg, and others, it was shown that bacteria solve this problem by sensing changes in attractant and repellent concentration in time rather than in space. In other words, chemotaxis depends on a temporal rather than a spatial sensing mechanism. As a cell moves it constantly compares its current surroundings to those it has experienced previously. If the comparison is favorable, the cell tends to keep going; if not, it tends to change direction. This mechanism implies a memory function whereby the present can be compared with the past to determine whether conditions are getting better or worse as time (and movement in a given direction) proceeds.

C. Excitation and adaptation

One of the ways it was shown that bacterial chemotaxis works by a temporal rather than spatial sensing mechanism was to suddenly transfer a population of randomly moving bacteria from one spatially uniform environment into another that contained a uniform distribution of an attractant or repellent chemical. In this type of experiment there are no spatial gradients; cells are exposed only to a temporal change in their environment. As expected from a temporal sensing mechanism, when cells are suddenly exposed

FIGURE 20.1. Chemotaxis is accomplished by a biased random walk mechanism. Bacterial swimming behavior involves a series of runs (indicated by arrows) punctuated by motor reversals that randomize the direction of the subsequent run. Cells migrate toward attractants and away from repellents by increasing their average run lengths in the preferred direction.

to attractants the entire population determines that it is on a good course and the tendency to change direction is uniformly suppressed (Fig. 20.2). The opposite effect is seen when cells are suddenly exposed to repellents. All the individuals in the population, despite the fact that they are moving many different ways, suddenly determine that they need to change the direction of their motion. This result clearly shows that bacteria must have a way of comparing the past with the present—they must have memory.

After a period of time, bacteria that have been transferred to a new environment gradually adapt so that their behavior returns precisely to the same random walk as that before they were exposed to the attractant or repellent stimulus. This occurs despite the fact that the attractant or repellent is still present. Thus, bacteria do not respond to absolute concentrations of attractant and repellent chemicals. They respond only to changes.

There is a close relationship between memory and adaptation. If one moves a population of bacteria that has adapted to an environment with an attractant back to an environment lacking attractant, the cells think they are moving in a bad direction so they all change course as if they had been exposed to a repellent. The opposite happens with cells that are adapted to a repellent. Thus, an increase in attractant concentration is equivalent to a decrease in repellent concentration and vice versa.

In bacterial chemotaxis, the sense and degree of excitation in response to a new place in time are only determined in relation to the memory of the old one, with the memory for the past environment being set by the process of adapting to it. In effect, there must be two core mechanisms at work in chemotaxis: an excitation mechanism that controls the probability of a motor reversal and an adaptation mechanism that

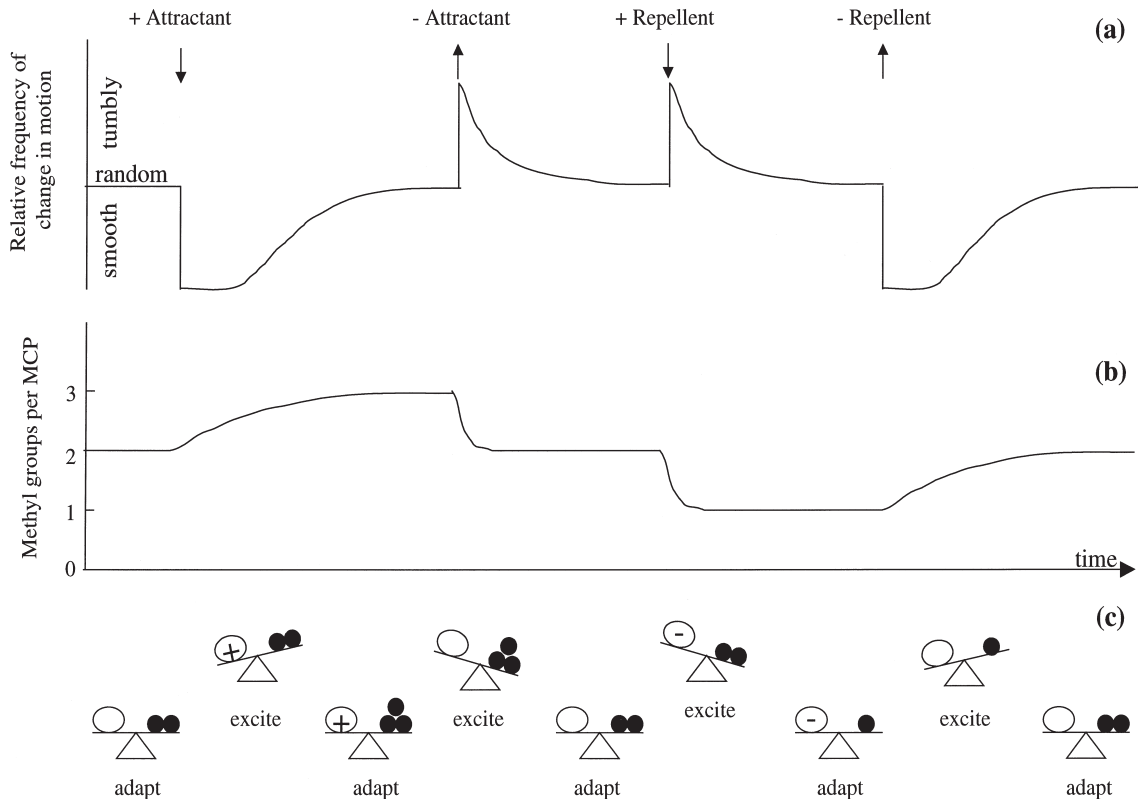

FIGURE 20.2 Excitation and adaptation in bacterial chemotaxis. (a) Addition of attractant causes cells to continue swimming smoothly without changing direction until they adapt back to their prestimulus random behavior, removal of attractant causes cells to frequently change direction or tumble until adaptation restores random behavior, adding repellent causes the same tumbling response as removing attractant, and removing repellent causes the same swimming response as adding attractant. (b) In the absence of attractants or repellents a typical MCP has approximately two of four possible methylated glutamates, addition of a saturating attractant stimulus causes addition of approximately one methyl group, removal of the attractant causes loss of this group, addition of a saturating repellent stimulus causes loss of one more methyl groups, and removal of repellent causes addition of a methyl group. (c) MCP signaling depends on the balance between stimulus (O, no stimulus; +, attractant; -, repellent) and the level of methylation (●, one methyl group; ●●, two methyl groups, etc.). A sudden change in stimulus causes an imbalance that leads to excitation, and the level of methylation then changes to restore the balance.

modulates the sense and degree of excitation with respect to a preset default value.

II. GENETICS OF BACTERIAL BEHAVIOR

A. Chemotaxis mutants

The most common strategy that has been used to isolate mutants that are defective in chemotaxis has involved selecting for cells that cannot swarm from a colony inoculated into the center of a dish filled with semisolid nutrient agar. Chemotactic cells form a colony at the point where they are initially inoculated, and the growing cells consume nutrients in the culture

media creating attractant gradients that cause them to swarm outward from the center. Mutant cells that are deficient in chemotaxis are left behind at the center. This strategy produces several different classes of mutant strains. By far the most common are strains that are not motile. In bacteria whose motility depends on flagella, these nonmotile strains can be subdivided into two classes: Fla mutants, which have lost the ability to make flagella, and Mot mutants, which make flagella that are paralyzed. Mutant strains that are unable to swarm but are fully motile are categorized into two additional subclasses: Che mutants, which are generally nonchemotactic, and blind mutants, which are unable to swarm in semi-solid agar with one type of nutrient but can swarm normally in agar that contains other nutrients.

B. Genetic analysis of *Escherichia coli* chemoreceptors

It was through the selection and characterization of blind mutants from *E. coli* that Julius Adler and colleagues first demonstrated that chemosensing in bacteria is mediated by specific receptors in the cell envelope rather than by some other mechanism such as nutrient utilization. The first chemoreceptors to be identified genetically were the galactose and ribose binding proteins that had previously been shown to function in the transport of their respective sugar ligands. The selection of ribose and galactose transport mutants with normal chemosensing abilities established that uptake and metabolism were not required for chemotaxis. Further genetic analysis indicated that ribose and galactose sensing required another component, termed Trg (taxis to ribose and galactose). Early work on the ribose and galactose receptors revealed another important aspect of chemotaxis—the possibility that bacterial cells could exhibit a simple form of learning. The galactose and ribose receptors are specifically induced by growth in the presence of galactose and ribose, respectively. Thus, whereas a naive cell is unable to respond to either sugar, once it is allowed to grow on ribose or galactose the corresponding receptor is induced and the cell has now learned to respond to that sugar.

In addition to the sugar receptors, Adler's group identified two *E. coli* genes, *tar* and *tsr*, that were required for responses to amino acids and several repellents. Tar was required for sensing of the attractants aspartate, glutamate, and maltose and the repellents cobalt and nickel. The maltose response also required an inducible maltose binding protein similar to the ribose and galactose binding proteins that had been shown to be mediated by Trg. Tsr was required for chemotaxis to serine, alanine, and several other amino acids and repellents. In contrast to the genes that encode binding proteins, *tar*, *tsr*, and *trg* are expressed in the same regulon as the flagellar genes of *E. coli* so that as long as a cell is motile it can sense aspartate and serine.

C. Che genes

The principal task of analyzing the *E. coli* Che mutants fell to a former colleague of Adler's, John S. Parkinson, who determined that there were two major Che complementation groups in *E. coli*, designated *cheA* and *cheB*. Later studies by Parkinson and others established that the CheA locus was composed of two genes (*cheA* and *cheW*), whereas the CheB locus was composed of four genes (*cheR*, *cheB*, *cheY*, and

TABLE 20.1 *E. coli* che genes

Gene	Protein <i>M_r</i> (kDa)	Function
<i>cheR</i>	32	Methylation of MCPs
<i>cheB</i>	36	Demethylation of MCPs
<i>cheW</i>	18	Coupling CheA to MCPs
<i>cheA</i>	73	Histidine kinase
<i>cheY</i>	14	CheY-P binds to flagellar switch to cause change in swimming direction
<i>cheZ</i>	24	CheY-P phosphatase

cheZ). Strains defective in *cheA*, *cheW*, *cheY*, or *cheR* exhibited a smooth swimming phenotype, never changing their direction of motion. In contrast, *cheB* and *cheZ* mutants had a constantly changing, tumbling pattern of swimming behavior. Whereas the ability of *cheB* and *cheZ* mutants to change direction was still suppressed by the addition of attractants, and *cheR* mutants could still reverse in response to repellent stimuli; *cheW*, *cheA*, and *cheY* mutants were completely unresponsive. From these results Parkinson was able to conclude that the CheW, CheA, and CheY proteins were essential for excitation, whereas CheR, CheB, and CheZ were involved in adaptation (for a summary of the Che genes and their protein products see Table 20.1). The fact that mutants defective in excitation were invariably smooth swimming suggested that the excitation mechanism produced a signal that caused a change in the direction of motion, and that in the absence of this hypothetical signal the cell would rarely, if ever, change its direction.

III. ROLE OF PROTEIN METHYLATION IN ADAPTATION

A. Methionine requirement for chemotaxis

One of the most important discoveries from Adler's pioneering work on the *E. coli* chemotaxis system was the serendipitous finding that methionine was required for chemotaxis. In his initial characterization of *E. coli* chemotaxis, Adler employed an assay that had first been developed in the late nineteenth century by the great German microbiologist and botanist, Pfeffer. This method, called a capillary assay, simply involves placing the tip of a glass capillary tube that contains an attractant chemical into a suspension of bacteria. As the attractant diffuses from the capillary tip, an attractant gradient is established which the cells follow up into the capillary tube. After about 1 hr the capillary is withdrawn and the bacteria inside are counted to provide a measure of the chemotaxis

response. Unlike with swarming on semisolid agar, capillary assays do not require cell growth, and they are generally performed with cells suspended in a defined buffer solution. Adler observed that when he performed this type of assay with a mutant *E. coli* strain that required methionine for growth, the chemotaxis responses to attractants were generally depressed. Among all the amino acids, this effect was specific for methionine. Further analysis showed that as cells became starved for methionine they lost the ability to adapt so that addition of attractants such as aspartate or serine caused a smooth swimming behavior similar to that observed with *cheR* mutants.

B. Methylaccepting chemotaxis proteins

Subsequent studies established that the effect of methionine depletion stemmed from a requirement for the universal methyl donor, *S*-adenosylmethionine (AdoMet), which is produced from methionine and ATP through the action of AdoMet synthase:

AdoMet is required for the methylation of a wide range of different macromolecules, including proteins, DNA, and RNA, as well as numerous different small molecules. It was shown that in chemotaxis the

requirement for AdoMet is to methylate a set of ~60-kDa membrane proteins that were termed methylaccepting chemotaxis proteins (MCPs). These proteins were identified with the products of genes such as *tar*, *tsr*, and *trg* that had been implicated in chemosensing. In fact, Tar and Tsr were shown to bind aspartate and serine, respectively, and to act directly as the membrane receptors for these attractants. Trg, on the other hand, acts indirectly as a receptor for ribose and galactose through interactions with the corresponding periplasmic binding proteins. Furthermore, maltose is detected by Tar via the periplasmic maltose binding protein. Thus, each MCP can detect several different stimuli either by binding a stimulatory ligand directly or through indirect interactions that are mediated by periplasmic binding proteins.

Methylation studies, analyses with anti-MCP antibodies, and, most important, DNA sequencing have shown that the MCPs are a large and highly conserved family of proteins that are invariably associated with bacterial chemosensing. There are five different MCPs encoded in the *E. coli* genome (Fig. 20.3), including Tar, Tsr, and Trg as well as a sensor for cellular redox potential termed Aer that is responsible for aerotaxis and a receptor that mediates responses to dipeptides termed Tap. Chemotaxis systems in other species of bacteria have an equivalent or larger number of different MCPs.

FIGURE 20.3 *Escherichia coli* chemoreceptors. There are five MCP receptors in *E. coli*: Tar, Tsr, Trg, Tap, and Aer. These transmembrane proteins either bind stimulatory ligands directly or interact with ligand-bound periplasmic binding proteins (MBP, maltose binding protein; RBP, ribose binding protein; GBP, galactose binding protein; DPP, dipeptide binding protein). Aer differs from other MCPs in that it has an intracytoplasmic sensing domain with an associated flavin cofactor, FAD. It is thought that Aer senses cellular oxidative potential through redox interactions with the electron transport system in the membrane.

C. Structural and functional organization of sensing and signaling domains of receptor MCPs

The MCPs are the principal sensory receptors of the bacterial chemotaxis system. They have a structural organization, membrane topology, and mode of function that is typical of type I receptors in all cells, including important vertebrate type I receptors such as the insulin, growth hormone, and cytokine receptors. In recent years, the Tar protein from *Salmonella typhimurium* has emerged as both the archetypal MCP and as a model to understand general principles of type I receptor function. Tar has the typical membrane topology of a type I receptor with an N-terminal extracytoplasmic sensing domain connected via a hydrophobic membrane-spanning sequence to an intracellular signaling domain. The sensing and signaling domains can function independent of the membrane and independent of one another. Most MCPs have this structural organization. Sequence comparisons indicate that, as one might expect, the extracytoplasmic sensing domains tend to be highly variable, whereas the cytoplasmic signaling domains, which interact with the Che proteins, are highly conserved. In fact, the tools of genetic engineering have been used to construct several different hybrid receptors with one MCP's sensing domain connected to another's signaling domain. In every case the hybrids exhibit sensory specificities equivalent to those of the MCP that contributed the N-terminal portion.

The sensory and signaling domains can also be produced as independent soluble protein fragments. This approach has been used with many type I receptors to produce protein fragments that are free of the membrane and can therefore be much more easily crystallized for X-ray diffraction studies. Determination of the X-ray crystal structure of the sensing domain of Tar in the presence and absence of aspartate revealed a dimer of two α -helical bundles with aspartate binding at the subunit interface.

The structure of the signaling domain has not been defined in detail, but it too is predominantly α -helical. The signaling domain is composed of a highly conserved central region that binds the CheW and CheA proteins and thereby connects the receptor to the remainder of the chemotaxis signal transduction system. This region is flanked on both sides by methylated α -helices that together contain four or more potential sites of glutamate methylation and demethylation. Attractants cause increases in the level of methylation and repellents cause decreases. These changes are responsible for adaptation to attractant and repellent stimuli (Fig. 20.2).

D. Receptor methylation enzymology

The MCP receptors are methyl esterified at several specific glutamate residues. The methylation reaction is catalyzed by an AdoMet-dependent methyltransferase encoded by the *cheR* gene. Receptor methyl groups are removed through the action of a specific methyl esterase encoded by the *cheB* gene. CheR and CheB are both soluble monomeric proteins. Their structures have recently been determined by X-ray crystallographic methods. CheR is tethered to Tar and Tsr via a tight interaction with the C-terminal four amino acids, which are identical in these two MCPs but are absent in Trg, Tap, and Aer. Tar and Tsr are present in cells at about 10-fold higher levels than Trg, Tap, and Aer, and considerable evidence suggests that the latter, so-called minor receptors, function in higher order complexes with the major receptors, Tar and Tsr. CheR tethering to major receptors puts the enzyme in position to methylate the associated minor receptors.

The active site of CheB contains a Ser-His-Asp catalytic triad that is characteristic of serine hydrolases. An N-terminal regulatory domain occludes the active site so that the enzyme is relatively inactive. CheB is activated to remove receptor methyl groups by the same signal that causes a change in the direction of cell movement in response to repellent stimuli. This provides a feedback mechanism that contributes to the adaptive phase of the chemotaxis response. Thus, repellent addition or attractant removal produce an excitatory signal to change direction. At the same time, this signal activates CheB, leading to a rapid decrease in the level of methylation that causes adaptation. The converse is true with attractant addition or repellent removal. It is as if the receptor signaling system functions as a balance between the effects of stimulatory ligands and methylation (Fig. 20.2). Addition of attractant or repellent offsets the balance to produce a positive or negative excitatory signal, and changes in methylation restore the balance to effect adaptation.

IV. MECHANISM OF SIGNAL TRANSDUCTION IN CHEMOTAXIS

A. Receptor-CheW-CheA signaling complexes

The CheA protein is a kinase that binds ATP and catalyzes the phosphorylation of one of its own histidine residues. The rate of autophosphorylation of the isolated CheA protein is very slow. The physiologically

relevant form of CheA seems to be in a stable complex with CheW and the MCP receptors. The rate of CheA autophosphorylation in these receptor-signaling complexes can be elevated at least 100-fold or completely inhibited depending on the level of receptor methylation and the binding of stimulatory ligands. Attractants such as serine or aspartate have an inhibitory effect, whereas increased levels of methylation cause dramatic increases in kinase activity. Because of the dimeric nature of the receptor sensing domain and the fact that CheA is a dimer, it was assumed that the receptor–CheW–CheA signaling complex had a 2:2:2 stoichiometry. Recent results indicate a much more complex architecture, with the thousands of receptors in a cell clustering together in a higher order complex with CheW and CheA (Levit *et al.*, 1998). It has been hypothesized that packing interactions within these signaling arrays function to control kinase activity in response to the binding of stimulatory ligands or changes in the level of receptor methylation.

B. Motor regulation and feedback control

The level of phosphorylation of the CheY protein controls the probability that a cell will change its direction of motion. CheY is a 14-kDa monomeric enzyme that catalyzes the transfer of a phosphoryl group from the phosphohistidine in CheA to one of its own aspartate residues. CheY phosphorylation induces a conformational change in the protein that causes it to bind to switching proteins at the flagellar motor. Repellent-induced increases in the rate of CheA phosphorylation produce elevated levels of phospho-CheY that bind to the motor to enhance the probability of motor reversal. Phospho-CheY spontaneously dephosphorylates to terminate the response. In *E. coli* this

autophosphatase reaction is dramatically enhanced by the CheZ protein. Thus, addition of attractants inhibits CheA autophosphorylation, and CheZ activity leads to a rapid decrease in the level of phospho-CheY, a reduction in the level of phospho-CheY bound to the motor, and a decrease in the probability that a cell will change direction.

The CheY protein is homologous to the regulatory domain of the CheB protein and, like CheY, the regulatory domain of CheB acts to transfer phosphoryl groups from the phosphohistidine in CheA to one of its own aspartate residues. Phosphorylation of CheB causes a dramatic increase in demethylation activity that leads to a decrease in receptor methylation and a concomitant decrease in the rate of CheA autophosphorylation. Thus, the same mechanism that acts to produce a motor response feeds back to cause adaptation. The signal transduction mechanism that mediates *E. coli* chemotaxis is summarized in Fig. 20.4.

V. PHYLOGENETIC VARIATIONS

Most of our understanding of bacterial chemotaxis has come from studies of the system in *E. coli*. Other motile bacteria that have been investigated have MCPs and all the same Che proteins as those in the *E. coli* system except for CheZ, which has only been found in enterics. There appear to be a number of variations on the *E. coli* scheme, however. Studies in *Bacillus subtilis* indicate that in this species the system is reversed so that attractants activate CheA, and CheY phosphorylation suppresses the tendency for the cell to change direction. The *B. subtilis* system also appears to have additional components that are not found in *E. coli*.

FIGURE 20.4. Biochemical interactions between the Che proteins that mediate chemotaxis responses in *E. coli*.

Many species have several copies of one or more of the chemotaxis genes. In some instances, it is apparent that there are multiple chemotaxis systems functioning in different cell types. The best example of this is provided by *Myxococcus xanthus*, in which different systems operate at different stages of development to control different types of motility. In contrast, two CheY proteins in *Rhodobacter sphaeroides* seem to supply divergent functions in one signal transduction network. One CheY interacts with the motor to control swimming behavior, whereas the other CheY functions as a CheA phosphatase to drain phosphoryl groups out of the system.

The chemotaxis system seems to be eubacterial in origin. There is no evidence for any of the chemotaxis components in eukaryotic cells. Although homologous systems are found in archaea such as *Halobacterium salinarum* and *Archaeoglobus fulgidus*, the sequences of the component proteins are so closely related to those of *B. subtilis* that one can be fairly certain that they originated by lateral transfer from a *B. subtilis* relative.

GLOSSARY

DNA supercoiling A phenomenon occurring in circular, covalently closed, duplex DNA molecules when the number of turns differs from the number found in DNA molecules of the same length but containing an end that can rotate. Supercoiling creates strain in closed DNA molecules. A deficiency of duplex turns generates negative supercoiling; a surplus generates positive supercoiling.

DNA topoisomerases Enzymes that change DNA topology by breaking and rejoining DNA strands. Topoisomerases introduce and remove supercoils, tie and untie knots, and catenate and decatenate circular DNA molecules.

nucleoid A term for the bacterial chromosome when it is in a compact configuration, either inside a cell or as an isolated structure.

origin of replication A location on the chromosome (*oriC*) where initiation of replication occurs. For *Escherichia coli*, *oriC* is approximately 250 nucleotides long, and during initiation it specifically interacts with several proteins to form an initiation complex.

recombination A process in which two DNA molecules are broken and rejoined in such a way that portions of the two molecules are exchanged.

replication fork The point at which duplex DNA separates into two single strands during the process of DNA replication. Associated with replication forks are DNA helicases to separate the strands and DNA polymerases to synthesize new DNA strands.

Bacterial Chromosomes are intracellular repositories of genetic information. In molecular terms, chromosomes are composed of (i) large DNA molecules that store information; (ii) RNA molecules in the process of copying information from specific genes; and (iii) proteins that repair DNA damage, duplicate the DNA, and control patterns of gene expression. Proteins also fold and bend the DNA so it fits in the cell. In many bacteria, chromosomal DNA appears to be circular, but examples of linear chromosomes have also been found. An individual cell can contain multiple identical copies of a single chromosome. Two and three distinct chromosome types have been observed in some species. When cells contain very large plasmids, the distinction between plasmid and chromosome blurs if both carry genes essential for cell growth. Chromosomal DNA has fewer duplex turns than would be found in linear, B-form DNA under the same conditions, and this deficiency of turns places torsional (superhelical) strain on the DNA. The strain lowers energy barriers for strand separation, and in this sense the chromosome is energetically activated. DNA replication begins at a precise point and continues bidirectionally until the two replication forks meet in a region 180° from the origin in circular DNA or until they reach the ends of linear DNA. As DNA is replicated, attached proteins pull the daughter chromosomes apart while other proteins untangle the DNA. Nucleotide sequence analysis of many bacterial genomes reveals that chromosomes have a rich evolutionary history of sequence rearrangements, which are due largely to fragments of DNA moving into and out of chromosomes.

I. HISTORICAL INTRODUCTION

Bacterial chromosomes were discovered much later than their eukaryotic counterparts because they do not exhibit the striking condensation at metaphase that makes eukaryotic chromosomes so easy to visualize. By the 1940s evidence that bacteria undergo spontaneous mutation finally emerged, and this established that bacteria must have mutable genes, the functional elements of chromosomes. At about the same time, Avery and associates uncovered the chemical nature of genetic material with a transformation experiment in which a character for polysaccharide synthesis was transferred from one strain of *Pneumococcus* to another using extracted DNA. At the time, the result was not universally accepted as evidence for genetic exchange, partly because the so-called "transforming principle," DNA, exerted its effect after an unknown number of steps and partly because there was no molecular framework for explaining how DNA could function as genetic material. In 1952, Hershey and Chase announced that phage DNA, not protein, is injected into bacterial cells during infection, and a year later Watson and Crick

provided the structural framework for DNA. At that point DNA became widely accepted as the carrier of hereditary information. By 1956, nucleoids, as bacterial chromosomes are sometimes called, could be seen in living cells as discrete, compact structures (a modern view is shown in Fig. 21.1). Gentle extraction methods eventually yielded large, intact DNA molecules, and by the early 1970s it became possible to isolate a compact form of the chromosome for biochemical study (Fig. 21.2). DNA supercoiling was discovered in the mid-1960s, and within a decade enzymes that introduce and remove supercoils had been characterized by Wang, Gellert, and Cozzarelli. The existence of these enzymes, DNA topoisomerases, gave credence to the idea that chromosomal DNA is under torsional tension. During the 1980s, the dynamic, regulated nature of supercoiling emerged as a major structural feature that needed to be considered whenever the activities of the chromosome were discussed. The development of rapid methods for determining nucleotide sequences led in the 1990s to complete sequences for many bacterial genomes. Information from DNA sequence analyses made it likely that all living organisms share a common ancestor, and inferences could be drawn about the nucleotide sequence history of chromosomes.

FIGURE 21.1 Bacterial nucleoids. Nucleoids of *Escherichia coli* K-12 were visualized in a confocal scanning laser microscope as developed by G. J. Brakenhoff (1985). Elongated cells were obtained by growth in broth. Then the nucleoids were stained with the DNA-specific fluorochrome DAPI (0.1 $\mu\text{g}/\text{ml}$) added to the growth medium. Under these conditions the stain had no effect on growth. The cells were observed either alive (a) or after fixation with 0.1% osmium tetroxide (b). Since the cell boundary is not easily visualized, it has been sketched in for reference (c). Multiple nucleoids were present because these fast-growing cells contain DNA in a state of multifork replication. In live cells, the nucleoid has a cloud-like appearance and a smooth boundary with the cytoplasm (protuberances, if present, would be smaller than 200 nm). Magnification = 9000 \times (courtesy of Dr. Conrad Woldringh, Department of Molecular Cell Biology, University of Amsterdam, The Netherlands).

FIGURE 21.2 Isolated bacterial chromosome. Electron micrograph of a purified, surface-spread *E. coli* chromosome. Photograph prepared by R. Kavenoff and O. Ryder; reprinted from *Chromosoma* by permission of the publisher. Bar represents 1 μm .

An emerging theme is the dynamic nature of bacterial chromosomes. In terms of nucleotide sequence, massive gene shuffling has occurred over the course of evolution. With respect to three-dimensional structure, portions of the genome move to particular regions of the cell at specific times during the cell cycle, even as the bulk of the DNA threads through stationary replication forks. At the level of DNA conformation, changes can occur within minutes after alteration of cellular environment. All three types of change are influenced, and in some cases directed, by protein components of chromosomes. In this article, we discuss major concepts concerning chromosome structure and point out unanswered questions. We conclude by describing a speculative model of the chromosome that may help put some of the details in perspective.

II. CHROMOSOME FORM AND NUMBER

Bacterial DNA has been found in both circular and linear forms. For *Escherichia coli*, chromosomal circularity is supported by three lines of evidence. First,

circles were observed when radioactively labeled DNA was extracted from cells and then examined by autoradiography. In these experiments almost all the molecules were so tangled that their configurations were unclear, but a few appeared as large circles more than 1 μm in length (cells are only 1 or 2 μm long). This chromosomal length is generally shorter than that expected from determination of the genomic nucleotide sequence. Second, genetic mapping studies are most easily interpreted as if the genes are arranged in a circle, although a linear interpretation is still possible (mapping can be ambiguous since a large linear bacteriophage DNA is known to have a circular genetic map). Third, two replication forks emerge from a single origin of replication and move bidirectionally toward a single terminus located 180° opposite the origin on the circular map. Replication data, which clearly reflect the whole cell population, are the strongest of the three lines of evidence. Conclusive evidence for circularity, which is still lacking, would be visualization of circular images of most of the DNA molecules present.

In 1989, chromosomal DNA molecules of *Borrelia burgdorferi* were found to have a linear form. Linear chromosomes were subsequently observed in *Streptomyces*

species, *Rhodococcus fasciens*, and *Agrobacterium tumefaciens*. With *Streptomyces*, DNA ends contain repetitive sequences as well as terminal proteins that prime synthesis complementary to the 3' end of the DNA. In *B. burgdorferi*, the ends are hairpins that facilitate complete replication. Thus, bacteria have chromosomal ends that function similarly to the telomeres of linear chromosomes in eukaryotic cells.

Many bacteria carry all their genes in a single genetic linkage group, as if they have a single type of chromosome. However, there is a growing list of species in which useful or essential genes are found on two or more chromosomes. The number of large, circular-mapping molecules is two for *Vibrio* species, *Deinococcus radiodurans*, *Leptospira interrogans*, *Rhodobacter sphaeroides*, and *Brucella* species, three for *Rhizobium meliloti*, and two to four among isolates of *Burkholderia* (*Pseudomonas*) *capecia*. Some *Agrobacterium* species contain one circular- and one linear-mapping chromosome. Thus, the idea that prokaryotes contain only one circular chromosome has been abandoned. Indeed, those with more than one chromosome (genetic linkage group) may constitute a sizable class since the vast majority of bacterial species has yet to be examined.

It is occasionally difficult to distinguish between chromosomes and plasmids since some plasmids are very large and contain genes essential for cell growth. Moreover, some large plasmids integrate into, and excise from, chromosomes. Thus, chromosome number in some species may be variable.

The existence of multiple copies of chromosomal regions, as well as entire chromosomes (multiploidy), is well-known in eukaryotes. In addition, a eukaryotic cell can contain thousands of copies of mitochondrial and chloroplast genomes. Multicopy genes and chromosomes are also common among bacteria. For example, *E. coli* contains approximately 11 genome equivalents per cell when growing rapidly in rich medium, whereas this number is between 1 and 2 during slow growth. In this organism high copy number may facilitate rapid cell doubling (see Section VII). For *Deinococcus radiodurans*, the ploidy levels are 10 during exponential growth and 4 during stationary phase; the corresponding values are about 7 and 3 for *Methanococcus janaschii*. Even slowly growing cells, such as *Borrelia hermsii* (minimum doubling time 8 h), can be multiploid. This bacterium contains 8–11 genome copies when grown *in vitro* and up to 16 copies when grown in mice. *Azotobacter vinlandii* represents a more extreme example. Its ploidy in rich medium increases from 4 to 40 and then to >100 as the culture progresses from early exponential through late exponential to stationary phase. Ploidy level then

decreases at the start of a new growth cycle. This spectacular increase in chromosome copy number in *Azotobacter* is not observed with cells grown in minimal medium. For the intracellular symbiont *Buchnera* the mean copy number increases to 240 (the range is 10–600) during development of its aphid host. The current record holder is *Epulopiscium fishelsoni*. Its DNA content varies by four or five orders of magnitude among individuals at different stages of the life cycle. Perhaps the increase represents an example in which DNA is used as a stored nutrient, much as fat and starch are used by other organisms. Another use for genome copies accumulated when nutrients are plentiful could be to supply genomes by dilution to smaller progeny cells when nutrients become limited, illustrating an "engorge now, divide later" strategy of cell proliferation. Regardless of the reason for polyploidy, it is clearly not restricted to eukaryotic cells. Indeed, bacterial and eukaryotic chromosomes can no longer be considered different with respect to form (both types can be linear), ploidy levels (both types can be multiploid), and number of linkage groups (bacteria, which often have one, can have several; eukaryotes, which usually have many, can have only one, as seen with the ant *Myrmecia pilosula*).

III. GENE ARRANGEMENTS

Gene mapping in bacteria was originally based on the ability of an externally derived, genetically marked fragment of DNA to recombine with the homologous region of a recipient's DNA. The frequency with which two nearby markers recombine is approximately proportional to the distance between them. Mutations were collected for a variety of purposes, and characterization usually included determining map position on the chromosome. The resulting genetic maps revealed relationships among genes such as operon clusters, showed orientation preferences that might reflect chromosomal activities, and suggested that some chromosomal information may have been derived from plasmids and phages. The discovery of restriction endonucleases led to a quantum advance in genetic mapping since these enzymes allowed the accurate construction of maps in terms of nucleotide distances. Practical nucleotide sequencing methods, which became available in the late 1970s, are rapidly yielding the complete nucleotide sequences for many bacterial species. Data are being obtained at three levels: (i) the genetic map, with the genes and their map locations correlated with the role of the gene products in cell metabolism, structure, or regulation; (ii) the physical map in terms of locations of

restriction sites; and (iii) the nucleotide and corresponding protein amino acid sequences. It is becoming clear that all living organisms probably arose from a common ancestor. Thus, information on nucleotide sequence and gene function in one organism can be applied to many other organisms.

One of the conclusions from genome studies is that large families of genes exist. For example, in *E. coli* there is a family of 80 membrane transport proteins, and half the protein-coding genes of *Mycobacterium tuberculosis* have arisen through duplication. These observations support the idea, which originated from analysis of eukaryotic genomes, that new genes arise from the duplication and modification of old ones.

The conservation of gene structure makes it possible to use nucleotide sequence information for comparison of genetic maps among bacterial species. One of the features revealed is clustering of related genes. For example, the genetic maps of *Bacillus subtilis*, *E. coli*, and *S. typhimurium* show a grouping of many genes for biosynthetic and degradative pathways. Such grouping could be for purposes of coordinated regulation since some adjacent genes produce polycistronic messages. A completely different view of the same data maintains that functionally related genes move horizontally (from one organism to another) as clusters because the products of the genes work well together, increasing the probability of successful transfer. Both ideas are likely to be accurate.

It is becoming increasingly clear that bacterial genomes can be quite malleable, even at the level of large rearrangements. For example, comparison of the genomic maps of *E. coli* and *S. typhimurium* reveals that a large inversion has occurred. Similar comparisons of *S. typhimurium* LT2 and *S. typhi* Ty2 show that these two genomes differ by at least three inversions. In a study of 21 *P. aeruginosa* isolates, nine inversions were detected.

Many comparisons make it possible to divide bacteria into two groups based on genomic stability. Representatives of the stable genome group are *E. coli*, *S. typhimurium*, and *Halobacterium salinarum*. Highly rearranged genomes are found in *S. typhi*, *Helicobacter pylori*, and *P. aeruginosa*. The reasons for differences among organisms are not clear. Some rearrangements, such as insertions or deletions, may be more deleterious for certain bacteria, or perhaps the opportunity for rearrangements, such as the occurrence of recombinational hot spots, is greater in some organisms than others. The latter explanation appears to be more likely for chloroplast and mitochondrial chromosomes, which in many ways resemble bacterial chromosomes. After approximately 300 million years of evolution, the order of chloroplast genes is highly conserved among most land plants,

including mung bean. However, chloroplast gene order is completely scrambled in pea, a plant closely related to beans. Massive rearrangement of genes is also evident when mitochondrial chromosome maps are compared among types of maize. Thus, gene order in organelles appears to have little functional significance, and it can be subject to frequent recombination if the opportunity arises.

As complete genomic nucleotide sequences become increasingly available, new questions will be raised. For example, what is the minimal number of genes required for independent life? Organisms of the genus *Buchnera* have the smallest cellular genomes, probably because many of the needs of these obligate symbionts are supplied by their hosts. Genomic comparison of the intracellular parasite, *Mycoplasma genitalium* with a free-living pathogen, *Hemophilus influenzae*, indicates that the minimal set of genes to sustain a cell may be approximately 250. Nucleotide sequences should also help identify genes involved in pathogenicity by comparison of virulent and avirulent strains of a pathogen. Such an approach has uncovered a "pathogenicity island," a collection of virulence genes, in *H. pylori*. The island is bounded by 31-base pair (bp) direct repeats, as if it had been transferred horizontally into an ancestor of *H. pylori*. In some bacteria, horizontal transfer may have been quite extensive. For example, in *E. coli* as much as 15% of the genome, (700 kbp) may have been acquired from foreign sources such as integrative bacteriophages, transposons in plasmids, and conjugative transposons (genetic elements that cannot replicate independently but cause conjugation, a form of cell-to-cell DNA transfer, to occur).

IV. RECOMBINATION

Intracellular DNA experiences a variety of perturbations that must be repaired to maintain the integrity of the genome and to allow movement of replication forks. Cells have several ways to repair DNA damage, one of which involves recombination (recombination is a process in which DNA molecules are broken and rejoined in such a way that portions of the two molecules are exchanged). Damaged sequences in one molecule can be exchanged for undamaged ones in another (Fig. 21.3). It is now thought that the *raison d'être* for recombination is its role in DNA repair, a process that may occur thousands of times per cell generation.

Recombination is also involved in DNA rearrangements arising from the pairing of repeated sequences. When the repeats are in direct orientation, duplications and deletions occur; inversions occur when the

FIGURE 21.3 Major pathways for recombinational DNA repair in bacteria. The principal function of recombination in bacteria is to restart replication forks stalled at sites of DNA damage. Two pathways are depicted. First, gap repair: (Ia) A DNA lesion blocks movement of the leading strand (ld), causing disassembly of the replication fork. (Ib) The RecA and RecFOR proteins replace the lesion with parental DNA from the lagging strand (lg) side of the fork by recombination. (Ic) The recombination intermediates are then resolved by the RuvABC and RecG proteins so replication can restart. Second, double-strand break repair: (IIa) A single-strand break (nick) blocks movement of the leading strand (ld), causing disassembly of the replication fork. (IIb) The RecA and RecBCD proteins regenerate the fork by recombination with parental DNA from the lagging strand (lg) side of the replication fork. (IIc) The recombination intermediates are then resolved and repaired by the RuvABC and RecG proteins so replication can restart (adapted from Cox, 1997, *Proc. Natl. Acad. Sci. USA* **94**, 11765, copyright 1997 National Academy of Sciences, USA).

repeat is inverted. In *B. subtilis* a cascade of sequential rearrangements has been identified in which large transpositions and inversions have been attributed to recombination at specific junction points in the chromosome. Several other examples are found with the *rrn* clusters, sets of similar assemblies of ribosomal and transfer RNA genes. Rearrangements at the three *rrn* clusters of *Brucella* are thought to be responsible for the differences in chromosome size and number among species of this genus. Other repeated sequences that facilitate rearrangements are the *rhs* loci (recombination hot spot), duplicate insertion sequences, and experimentally introduced copies of the transposon Tn10.

A third consequence of recombination is the insertion of genes from mobile elements into chromosomes.

These elements, which include transposons, plasmids, bacteriophages, integrons, and pathogenicity islands, move from one cell to another and sometimes from one species to another. In a spectacular example of gene transfer and its evolutionary effects across kingdoms, the acquisition of a symbiosis island of 500 kbp converts a saprophytic *Mesorhizobium* into a symbiont of lotus plants. Because they mediate such sweeping change, mobile genetic elements may represent the most important means for generating the genetic diversity on which selection operates. For mobility, and thus generation of genetic diversity, such genetic elements require recombination activities.

V. DNA TWISTING, FOLDING, AND BENDING

A. DNA supercoiling

Circular DNA molecules extracted from bacteria that grow at moderate temperature have a deficiency of duplex turns relative to linear DNAs of the same length. The deficiency places strain on DNA, causing it to coil. This coiling is loosely referred to as negative supercoiling (an excess of duplex turns would give rise to positive supercoiling). The strain is spontaneously relieved (relaxed) by nicks or breaks in the DNA that allow strand rotation; consequently, supercoiling is found only in DNA molecules that are circular or otherwise constrained so the strands cannot rotate. Since processes that separate DNA strands relieve negative superhelical strain, they will tend to occur more readily in supercoiled than in relaxed DNA. Among these activities are initiation of DNA replication and initiation of transcription. Negative supercoiling also makes DNA more flexible, facilitating DNA looping, wrapping of DNA around proteins, and the formation of cruciforms, left-handed Z-DNA, and other non B-form structures. In a sense, negatively supercoiled DNA is energetically activated for most of the processes carried out by the chromosome.

Negative supercoils are introduced into DNA by gyrase, one of several DNA topoisomerases found in bacteria. DNA topoisomerases act through a strand breaking and rejoining process (Fig. 21.4) that allows supercoils to be introduced or removed, DNA knots to be tied or untied, and separate circles of DNA to be linked or unlinked. The effect of gyrase is modulated by the relaxing activity of topoisomerase I. Since gyrase is more active on a relaxed DNA substrate and topoisomerase I on a highly negatively supercoiled one, the two topoisomerases tend to reduce variation

FIGURE 21.4 Negative supercoils. Gyrase generates negative supercoils by passing one duplex strand through the other. In the scheme shown, the enzyme binds to the DNA and creates a positive and a negative node (a). At the upper, positive node the duplex is broken (b). The bottom strand is then passed through the break, which is then sealed (c). [Reprinted from *Trends in Genetics* 6, Drlica, Bacterial topoisomerases and the control of DNA supercoiling, p. 433, copyright 1990, with permission from Elsevier Science.]

in supercoiling under stable growth conditions. In addition, lowering negative supercoiling increases gyrase expression and decreases topoisomerase I expression. Thus, negative supercoiling is a controlled feature of the chromosome.

Supercoiling is influenced by the extracellular environment. For example, when bacteria such as *E. coli* are suddenly exposed to high temperature, negative supercoiling quickly drops (relaxes), and within a few minutes it recovers. The reciprocal response is seen during cold shock. Presumably these transient changes in DNA supercoiling facilitate timely induction of heat and cold shock genes important for survival. Supercoiling is also affected by the environment through changes in cellular energetics. Gyrase hydrolyzes ATP to ADP as a part of the supercoiling reaction; ADP interferes with the supercoiling activity of gyrase while allowing a competing relaxing reaction to occur. Consequently, the ratio of [ATP] to [ADP] strongly influences the level of supercoiling reached. Changes in oxygen tension and salt concentration are examples in which cellular energetics and supercoiling change coordinately. Collectively, these observations indicate that chromosome structure changes globally in response to the environment.

Supercoiling is influenced locally by transcription. During translocation of transcription complexes along DNA, RNA polymerase does not readily rotate around DNA. Consequently, transcription generates positive supercoils in front of complexes and negative supercoils behind them. Since topoisomerase I removes the negative supercoils and gyrase the positive ones, transcription and similar translocation processes have only transient effects on supercoiling. However, there are cases in which induction of very high levels of transcription results in abnormally high levels of negative supercoiling. In such situations transcription-mediated changes in supercoiling

provide a way for specific regions of a DNA molecule to have levels of supercoiling that differ greatly from average values. Problems can occur because excessive negative supercoils behind a transcription complex allow nascent transcripts to form long hybrids with the coding strand of DNA. Such structures, called R-loops, probably interfere with gene expression. Problems also occur as a result of a buildup of positive supercoils in front of a transcription complex since helix tightening will slow transcription. This is probably why strong gyrase binding sites are scattered throughout the chromosome immediately downstream from active genes.

B. Chromosome folding

Multiple nicks are required to relax chromosomal supercoils. Consequently, it was concluded that the DNA must be constrained into topologically independent domains. Current estimates place the number at approximately 50 domains per genome equivalent of DNA in *E. coli*, or approximately 1 per 100 kbp of DNA. Since superhelical tension and topological domains are detected in living cells, it is unlikely that the domains are an artifact of chromosome isolation. From a functional point of view, dividing the chromosome into domains prevents a few DNA nicks or gaps from relaxing supercoils in the entire chromosome. The existence of domains also makes it possible to introduce supercoils into the chromosome before a round of replication finishes; in the absence of domains, the gaps following replication forks would relax any supercoils that gyrase might introduce. Thus, the domains allow the bulk of the chromosome to maintain a supercoiled state.

How the domains are established is unknown. They are present after cells are treated with rifampicin, an inhibitor of RNA synthesis; thus, they are not simply the by-products of DNA–RNA polymerase–RNA complexes. Even after exhaustive deproteinization, fluorescence microscopy shows that nearly every nucleoid in preparations from both exponential- and stationary-phase *E. coli* appears as a rosette or loose network of 20–50 large loops. Networks probably also occur in the linear chromosomes of *B. burgdorferi*. When examined by pulsed-field gel electrophoresis and fluorescence microscopic imaging of individual DNA molecules, some, and occasionally most, of the DNAs are in an electrophoretically immobile network larger than the size of the genome (some *B. burgdorferi* DNA also behaves as unit length linear molecules). Discovering the nature of the bonding in the apparently all-DNA networks may be central to understanding bacterial chromosome structure.

C. DNA bending

Associated with the *E. coli* chromosome are five small proteins that either bend DNA or bind to bends and stabilize them. The most abundant is HU, a protein with long flexible arms that reach around DNA and force it to make a U-turn. HU does not recognize a specific nucleotide sequence; therefore, it is considered to provide a general bending activity. Several examples have been found in which HU serves as an architectural protein, assisting in the formation of DNA-protein complexes that carry out site-specific recombination. HU also provides the DNA bending needed for certain repressors to bring distant regions of DNA together in loops that block initiation of transcription.

HU was initially classified as a histone-like protein on the basis of its amino acid composition and its ability to wrap DNA into nucleosome-like particles *in vitro*. Nucleosomes, which have long been a distinctive feature of eukaryotic nuclei, are ball-like structures in which approximately 200 bp of DNA is wrapped around histone proteins. Nucleosomes occur at regular intervals along DNA, giving nuclear chromatin a "beads-on-a-string" appearance and compacting the DNA by a factor of approximately seven. True bacteria (eubacteria) do not have true histones or nucleosomes, although some archaeobacteria (archaea) do. It is unknown whether HU wraps intracellular DNA or just bends it.

Closely related to HU is a bending protein called IHF (integration host factor). It too can cause DNA to turn 180° on itself, but unlike HU, IHF recognizes specific nucleotide sequences. There are many examples in which IHF helps form a DNA loop between promoters and transcription activators bound far upstream from promoters, thereby facilitating initiation of transcription. IHF also participates as an architectural protein during the formation of site-specific DNA-protein complexes. The best known of these is the intasome generated by bacteriophage lambda during integration into the bacterial chromosome.

Two other bending proteins, factor for inversion stimulation (FIS) and leucine-responsive regulatory protein (LRP), serve as sensors and global regulatory agents. FIS senses the bacterial growth phase, and its expression is sharply elevated shortly after a culture begins growing. In older cultures the rate of FIS synthesis decreases to almost zero. FIS binds to specific nucleotide sequences, some of which are so close to a promoter that FIS acts as a repressor. In other cases, FIS acts as an upstream activator of transcription. LRP responds to the nutrient status of the cell, particularly amino acid levels. It acts as a repressor for many

genes involved in catabolic (breakdown) processes and an activator for genes involved in metabolic synthesis. Both FIS and LRP also have architectural roles when they bend DNA to form protein-DNA complexes for site-specific recombination.

The fifth protein is called H-NS (histone-like nucleoid structuring protein). Unlike the other four, it does not actively bend DNA. Instead, it binds to DNA that is already bent. If an appropriate bend is near the promoter of a gene, H-NS will bind and act as a mild repressor. It is likely that 100 genes are affected in this way. H-NS action appears to be a general way to keep the expression of many genes down-regulated until their products are needed.

It is not known whether a bending protein is involved in packaging the chromosome as a whole. It is interesting to note that when H-NS is expressed at very high levels, the chromosome compacts. Although such an event is lethal, it may reflect a moderate compacting action by H-NS at normal concentration. Also relevant may be the observation that cells do not tolerate the absence of HU, IHF, and H-NS together, although cells are viable when only one of the three proteins is present. Perhaps at least one of these DNA-bending proteins is needed for chromosome compaction.

VI. CHROMOSOME INACTIVATION

In eukaryotic cells large portions of genomes are rendered transcriptionally inactive by heterochromatinization, a local DNA compaction that is readily observed by light microscopy. Bacterial chromosomes are too small for locally compacted regions to be seen; consequently, we can only guess about their existence. However, evidence is accumulating that bacteria have systems that condense entire chromosomes. In *Caulobacter crescentus* two cell types exist: swarmer cells and stalk cells. When a swarmer cell differentiates into the stalked form, the nucleoid changes from a compact to a more open structure, possibly reflecting an activation of the genome. In a second example, a histone H1-like protein in *Chlamydia trachomatis* probably causes chromosomal condensation during the conversion of the metabolically active reticulate body to the inactive, extracellular elementary body form. Another example occurs during sporulation in *Bacillus*. In this case the chromosome of the spore is bound with new proteins as its transcriptional activity ceases. Still another case is when the cells of the archaeobacterium *Halobacterium salinarium* progress from early to late exponential phase of growth. In this prokaryote, the nucleoid obtained by gentle lysis

procedures changes from a form containing naked DNA to one having a beads-on-a-string appearance typical of nucleosomal DNA; this change, seen by electron microscopy, is also reflected in nucleoid sedimentation properties. Finally, fluorescence measurements of DNA and RNA within the enormous cells (up to 500 μm long) of *Epulopiscium fishelsoni* suggest that decondensation and dispersion of the nucleoid are accompanied by increased transcriptional activity. As tools with sufficient resolution become available, it should be possible to determine whether the subchromosomal condensation-decondensation strategy of gene regulation in eukaryotic cells also exists in bacteria.

VII. CHROMOSOME DUPLICATION

The major features of chromosome replication have been established for many years. Semiconservative replication was demonstrated by density-shift experiments in 1958, and a few years later the autoradiograms prepared by Cairns revealed a partially replicated circle containing a large replication "eye." In the early 1970s it became clear that bidirectional replication begins at a fixed origin (*oriC*) and that the two forks proceed in opposite directions until they reach a terminus 180° from *oriC* on the circular map. Under conditions of rapid growth, bacterial chromosomes can contain more than one pair of replication forks. It is the presence of multiple forks that allows multiple chromosomes to be present, which in turn enables *E. coli* cells to double at shorter intervals than required for the forks to traverse the chromosome.

The isolation of heat-sensitive mutations in genes called *dnaA* and *dnaC* made it possible to uncouple initiation from the elongation phase of replication. Then the origin (*oriC*) was cloned by its ability to confer replication proficiency to a plasmid lacking an origin of replication. The availability of the origin on a small piece of DNA and purified initiation proteins allowed Kornberg to develop an *in vitro* initiation system. From this system it was learned that initiation involves the specific binding of the DnaA protein to *oriC* and the wrapping of origin DNA around DnaA. Local DNA strand separation then occurs at the origin, and single-stranded binding protein attaches to the separated strands. This helps stabilize what appears to be a single-stranded bubble in duplex DNA. The DnaB helicase, helped by the DnaC protein, binds to the replication bubble and enlarges it. Then DNA polymerase binds, and new strands are

synthesized as one replication fork moves away from the origin in the clockwise direction and a second fork moves in the counterclockwise direction.

Several factors prevent a second round of replication from beginning immediately after the first. One is the need for negative supercoils. During the elongation phase of DNA replication nicks and gaps are present in DNA undergoing lagging strand synthesis. These interruptions in DNA are eventually sealed, but while they are present they relax any supercoils introduced by DNA gyrase. Another restriction is mediated by the SeqA protein. It binds tightly to hemimethylated DNA sites near *oriC* and is thought to prevent the DnaA protein from binding to *oriC*. Eventually these sites become fully methylated and available for DnaA binding. These processes, plus interactions with several other proteins, make initiation of replication a highly regulated process.

Termination of replication is also complex. When the replication forks reach a position about half-way around the circular map from *oriC*, they encounter nucleotide sequences called *ter*. The *ter* sequences act as binding sites for a protein that impedes the movement of the DNA helicases associated with replication. Since the replication apparatus (replisome) is likely to be a large structure, the two converging forks might not completely replicate the chromosome. That task may be left to DNA repair enzymes that can unwind the double helix and replicate short regions. The unwinding process can leave circular molecules interlinked (long linear DNA could be locally interlinked due to constraint of strand rotation by chromosomal proteins). DNA topoisomerase IV appears to be the major unlinking (decatenating) activity (bacteria that lack this enzyme probably use DNA gyrase to decatenate their chromosomes; when nicks or gaps are present, topoisomerases I and III can decatenate interlinked circles).

Sensitive probes for specific regions of the chromosome have provided support for two major cytological concepts. First, fluorescent labeling of DNA polymerase revealed that replication forks are located at the center of the cell, where they appear to remain throughout most of the cell cycle. When multifork replication occurs, two additional replication centers, each probably containing a pair of forks, can be seen situated between the mid-cell forks and the cell poles. What holds the replication apparatus in place is unknown, although circumstantial evidence implicates an attachment to the cell membrane. The fixed nature of replication forks supports the idea that replicating bacterial DNA threads through a stationary replication apparatus, a notion that has long been advocated for eukaryotic cells.

The second concept focuses on the movement of *oriC*. The region can be visualized microscopically by treating cells with fluorescent antibodies directed at proteins that bind to repeated nucleotide sequences placed near *oriC* (or any other specified region). In newly formed cells, *oriC* and the replication terminus are located at opposite poles of the nucleoid. During replication, *oriC* moves briefly toward a mid-cell position. Then two copies of *oriC* become visible at the nucleoid pole, apparently having been drawn back after replication. Later, one copy abruptly moves to the opposite edge of the nucleoid. The replication terminus then migrates to a mid-cell position, and late in the cell cycle two termini can be seen pulling apart. The septum that separates the new daughter cells forms between the termini. The localization of *oriC* and its rapid movement, which is about 10 times faster than cell elongation, indicate that bacterial chromosomes undergo a form of mitosis.

Although the details of bacterial "mitosis" are poorly understood, several proteins exhibit properties expected of mitotic proteins. For example, in *B. subtilis* the Spo0J protein appears to participate in chromosome partitioning by binding to multiple sites on the chromosome near, but not at, *oriC*. Ten related, 8-bp inverted repeat DNA sequences are scattered across approximately 800 kbp of the 4200-kbp chromosome. Eight of these sites are bound *in vivo* to Spo0J. Such distribution of bacterial centromere-like DNA elements is similar to the most common type of distribution of functional centromeric DNA in eukaryotes, the *CEN*-containing regional centromeres. Thus, Spo0J may hold the new and old copies of *oriC* near one pole of the nucleoid until one copy of *oriC* is moved to the opposite pole. Chromosome condensation, which is probably too slight to see with current methods, may involve the action of the Smc protein, a homolog of a eukaryotic protein family known to participate in DNA condensation. When *smc* is mutant in *B. subtilis*, the Spo0J protein is not found at its polar position on the nucleoid, and newly formed septa cut some daughter chromosomes in a guillotine-like manner.

The extrusion of newly replicated DNA from the centrally-located replisome may provide some organization to the chromosome: genes located near *oriC* on the genetic map are also positioned near *oriC* in the cell. Likewise, genes mapping near *ter* are spatially located near the terminus of replication.

As replicated chromosomes are pulled apart, DNA tangles must occur. The double-strand passing activities of gyrase and topoisomerase IV are well suited to resolve the tangles. Consistent with this idea, both enzymes are distributed around the *E. coli* chromosome, as judged by DNA cleavage induced by the

quinolone inhibitors of topoisomerases. In *E. coli*, DNA cleavage occurs at approximately 100-kbp intervals for gyrase and 200-kbp intervals for topoisomerase IV.

VIII. SPECULATIONS ON CHROMOSOME PACKAGING DYNAMICS

In the past two decades, our understanding of bacterial chromosomes has advanced remarkably along two fronts. First, a combination of genetics and biochemistry has taught us a great deal about the proteins that manipulate DNA. Second, we now have complete genomic sequences for many bacteria. These sequences indicate that bacterial genomes are quite flexible with respect to gene order. However, few experiments bear on how the long chromosomal DNA molecule is compacted to fit inside a cell. Here, we offer a speculative scheme that may help form a framework for understanding future discoveries.

One key concept is that cytoplasmic proteins and other large cytoplasmic molecules are at such high concentration that they compact DNA through macromolecular crowding. This idea, which has recently been refined by Zimmerman, requires no specific DNA compacting proteins, and so it accommodates the apparent absence of nucleosome-like particles in eubacteria. We envision that chromosomal activities involving bulky protein complexes occur at the edges of the nucleoid (Fig. 21.5). For example, the replication apparatus, which is likely to be attached to a multienzyme complex that supplies deoxyribonucleoside triphosphates, is probably situated at the edge of the compacted portion of the chromosome, especially if replication proteins are bound to the cell membrane. Likewise, transcription, which in bacteria is coupled to translation, also probably occurs on DNA emerging from the compacted mass of nucleoid DNA because ribosomes are seen only outside the nucleoid (extrachromosomal localization is especially likely when transcription-translation complexes are bound to the cell membrane via nascent membrane proteins). Consistent with this idea, pulse-labeled nascent RNA is preferentially located at the nucleoid border, as is topoisomerase I (as noted previously, topoisomerase I may serve as a cytological marker for transcription since it is probably localized behind transcription complexes to prevent excess negative supercoils from accumulating).

If the replication and transcription-translation machinery are located on the surface of the nucleoid,

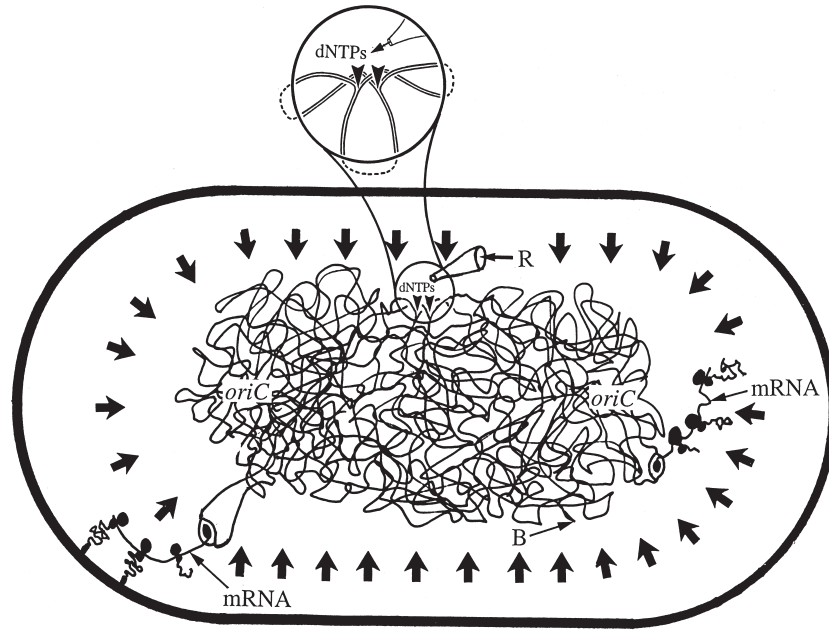

FIGURE 21.5 Overview of bacterial chromosome structure. The figure shows a schematic representation of a bacterial cell and its chromosomal DNA (nucleoid). The replication apparatus is located at the edge of the nucleoid at a mid-cell position. Two replication forks (arrowheads) are shown in close proximity. DNA is thought to thread through a stationary replication apparatus. The funnel-like structure represents a multienzyme complex responsible for synthesis of deoxyribonucleoside triphosphates (dNTPs) from ribonucleoside diphosphates (R). In the enlargement of the replication apparatus the dashed lines outside the circle represent the connections between the DNA strands masked by the large amount of DNA in the cell. The polar distribution of *oriC* regions is indicated. Macromolecular crowding (arrows) contributes to DNA condensation, with additional packing occurring from protein-induced DNA bending (B) at many points on the chromosome (only one bending point is labeled). Two examples of coupled transcription–translation are shown to occur at the edge of the nucleoid. In the lower left, nascent protein is bound to the cell membrane, drawing a region of DNA out of the compact part of the nucleoid. To provide transcriptional access to all regions of the genome, the interior and exterior regions of the nucleoid are assumed to exchange rapidly.

DNA movement must occur to allow access to all nucleotide sequences. Replication-based movement probably occurs by DNA threading through stationary replication forks. Such movement would not be sufficient for transcriptional access to the whole genome since some genes can be induced when DNA replication is not occurring. Perhaps compacted DNA is sufficiently fluid that genes frequently pass from interior to exterior. At any given moment, in some fraction of the cell population each gene may be at the surface of the nucleoid and available for transcription. Capture of a gene by the transcription–translation apparatus would hold that gene on the surface. During induction of gene expression, the fraction of cells in which a particular gene is captured would increase until most of the cells express that gene. For the chromosome as a whole, many genes would be expressing protein during active growth, and therefore many regions would be held outside the nucleoid core by the transcription–translation apparatus. Kellenberger suggested that such activity explains why the nucleoid appears more compact when protein synthesis is experimentally interrupted. The idea of gene capture for expression requires that the replication apparatus be strong

enough to pull the DNA through itself even when genes are bound to ribosomes via mRNA and to the cell membrane via nascent proteins still attached to ribosomes. A fixed RNA polymerase must also pull DNA.

Capture of the *oriC* region by the replication apparatus might be similar to gene capture for transcription. With the fluid chromosome hypothesis, some replication proteins would assemble at mid-cell, whereas others would assemble with the centromere-like DNA elements and Spo0J (in *B. subtilis*) at the poles and dislodge *oriC* from its polar connection. Once liberated, a mobile *oriC* would be captured by the replication apparatus at mid-cell. As *oriC* and nearby regions are drawn through the replication forks and replicated, new binding sites for a chromosome partition protein (Spo0J) would be created. Once these sites were filled, the two daughter *oriC* regions might pair through Spo0J–Spo0J interactions and return to the polar position. Other proteins would later disrupt the Spo0J–Spo0J interactions as the new Spo0J–*oriC* complex is moved to the other pole of the nucleoid.

Movement of DNA must generate tangles, just as loops in fishing line snarl when reels are not carefully

attended. The decatenating activities of the type II topoisomerases, DNA gyrase and topoisomerase IV, are available to remove the tangles, explaining in part why these two enzymes are found at many spots on the chromosome. The movement of the daughter chromosomes to opposite cell poles would provide the directionality needed by the topoisomerases to untangle the loops.

The abundant DNA bending proteins, such as HU, IHF, and H-NS, probably facilitate chromosome compaction in a dynamic manner by rapidly exchanging between DNA-bound and unbound states. Likewise, the topoisomerases probably respond rapidly to local perturbations in supercoiling to maintain the proper level of supercoiling throughout the chromosome.

Fixed topological domains are not easily accommodated by a fluid model for bacterial chromosome structure, since they require specialized, pulley-like structures to allow the DNA movement needed for replication. Transient domains could be generated by recombination intermediates, provided that recombination occurs often enough to maintain approximately 50 domains per genome.

IX. CONCLUDING REMARKS

Many of the features found in bacterial chromosomes are remarkably similar to those of eukaryotic chromosomes: linear maps, one or more dissimilar chromosomes [the number can be as high as four among bacteria and as low as one in eukaryotes ($2N = 2$)], high ploidy (copy number) levels, and a mitotic-like apparatus used in cell division. Consequently, the prevalent belief that profound differences exist between prokaryotic and eukaryotic chromosomes is gradually eroding. A major distinction, other than the presence of a nuclear membrane in eukaryotes, revolves around histones and their compaction of DNA into nucleosomes. True bacteria lack histones and nucleosomes, and so DNA compaction must occur by other means. However, some archaea have histones and stable nucleosomes, whereas some unicellular eukaryotes lack both. Thus, at the chromosome level the difference between prokaryotes and eukaryotes may not be as extensive as generally thought.

ACKNOWLEDGMENTS

We thank M. Gennaro and G. L. G. Miklos for critical comments on the manuscript. The authors' work was supported by grants from the National Science

Foundation, the American Cancer Society, and the National Institutes of Health.

Conjugation, Bacterial

Laura S. Frost

University of Alberta

GLOSSARY

plasmid An extrachromosomal DNA segment, usually circular, which is capable of autonomous replication via a segment of the plasmid called the replicon.

transconjugant A general term for a recipient cell that has successfully been converted to donor cell by conjugation.

transposon A segment of DNA that is replicated as part of a chromosome or plasmid. It encodes a mechanism, called transposition, for moving from one location to another, leaving a copy at both sites.

Bacterial Conjugation was first described by Lederberg and Tatum in 1946 as a phenomenon involving the exchange of markers between closely related strains of *Escherichia coli*. The agent responsible for this process was later found to be a site on the chromosome called the F ("fertility") factor. This finding was the basis of bacterial genetics in the 1940s and 1950s and was used extensively in mapping the *E. coli* chromosome, making it the pre-eminent prokaryotic organism at that time. It was also shown that F could excise out of the chromosome and exist as an extrachromosomal element which was capable of self-transfer to other bacteria and that mobilization of the chromosome was the serendipitous function of F integrated randomly into its host's DNA. The F sex factor of *E. coli* also imparted sensitivity to bacteriophages which required the F pilus, encoded by the F transfer region, as an attachment site during infection.

In the 1960s many other conjugative plasmids were isolated, many of which carried multiple antibiotic

resistance markers. These plasmids were termed R ("resistance") factors and were found in many instances to repress pilus expression and conjugation by F, a process termed fertility inhibition (fi^+). The number of conjugative plasmids has increased tremendously in the past few decades and includes self-transmissible plasmids isolated from gram-negative and -positive bacteria as well as mobilizable plasmids. Conjugative transposons and members of the IncJ incompatibility group move between cells using a conjugative mechanism, whereby they excise and integrate into the host chromosome via a process reminiscent of lysogenic phage. An example of true conjugative phages include one from *Staphylococcus aureus* and the STX element of *Vibrio cholera*. These elements might more precisely be called conjugative genomic islands since they are conjugative, self-transmissible and are obligatory residents of the host chromosome.

In general, the transfer and replication functions of these mobile elements are often physically linked and the type of transfer system is closely aligned with the nature of the replicon which is described by incompatibility groups (Inc). An excellent summary of the properties of many conjugative plasmids is given in Shapiro (1977).

Bacterial conjugation is now known to be one of the principal conduits for horizontal gene transfer among microorganisms. The process is extremely widespread and can occur intra- and intergenerically as well as between kingdoms (bacteria to yeast, plants or animal cells). The effect of this process on evolution

has been immense, with bacteria rapidly acquiring traits both good (hydrocarbon utilization) and bad (antibiotic resistance, toxins). The sequences of bacterial genomes has revealed many genomic islands containing homologues of conjugative systems which have been shown to be involved in protein and DNA transfer between cells, protein secretion and DNA excretion and uptake during transformation. While the mechanism for this extraordinary versatility in substrate transport remains undetermined, these homologous systems are known collectively as Type IV secretion (Christie, 2001) which is not to be confused with Type II secretion that elaborates a Type IV pilus. Type IV secretion systems also often elaborate a pilus, such as the conjugative pilus of gram-negative transfer systems, which has been classified as Type II (Ottow, 1975). Once again, bacterial conjugation is at the forefront of microbiology, but this time the emphasis is on the process rather than its utility as a geneticist's tool. Excellent summaries of related topics are provided in books by Clewell (1993) and Thomas (2000).

I. THE CONJUGATIVE PROCESS

Unlike the other processes contributing to horizontal gene transfer, transformation, and transduction, conjugation can be characterized by two important criteria. There must be close cell-to-cell contact between the donor and recipient cells and DNA transfer must begin from a specific point on the transferred DNA molecule, be it a plasmid, transposon, or chromosome (Fig. 22.1). This point is encoded within the origin of transfer (*oriT*) called *nic*. The proteins which act on these sites are encoded by *tra* (transfer) or *mob* (mobilization) regions. In general, each conjugative element encodes an array of proteins for mating pair formation (Mpf), whereas another set of proteins are involved in processing and transferring the DNA (Dtr). The Mpf genes can further be classified into the genes for pilus formation and mating pair stabilization (Mps) in gram-negative bacteria or aggregate formation in gram-positive cocci. A system to prevent close contact between equivalent donor cells is called surface exclusion. The gene products that process the DNA in preparation for transfer usually include a protein (relaxase) that cleaves the DNA in a sequence- and strand-specific manner at *nic* and remains covalently bound to the 5' end in all cases that have been examined. This nucleoprotein complex, plus other auxiliary proteins bound to the *oriT* region, is called the relaxosome, whereas the complex formed by the transport machinery is known as the transferosome.

FIGURE 22.1 Summary of the mating process for universal (plasmid F) and surface-preferred (plasmid RP4) conjugation systems in gram-negative bacteria and the pheromone-activated system of *Enterococcus faecalis* (plasmid pCF10). In universal systems, the pilus attaches to a receptor on the recipient cell surface (1) and retracts to form a stable mating pair or aggregate (2). DNA transfer is initiated (3), causing transport of a single strand in the 5' to 3' direction (4). Transfer is associated with synthesis of a replacement DNA strand in the donor cell and a complementary strand in the recipient (5). The process is terminated by disaggregation of the cells, each carrying a copy of the plasmid (6). The transfer systems of conjugative plasmids in gram-negative bacteria can be repressed (7) or derepressed (constitutive; 8). Cells carrying RP4 and related plasmids express pili constitutively but the pili are not seen attached to the bacteria. Such cells form mating pairs by collision on a solid surface (8). In gram-positive bacteria, such as the enterococci, the donor senses the presence of pheromone (*), released by the recipient cell, which triggers mating pair formation and DNA transfer (9). Donor cells are shown as oblongs and recipient cells as ovals.

A process which prevents the transfer of DNA into the recipient cell after Mpf has occurred is called entry exclusion. Previously, surface and entry exclusion were used interchangeably; however, as the details of the process are refined, it is important to make this distinction.

In gram-negative bacteria, the process of DNA transfer is triggered upon cell contact, whereas in *Enterococcus faecalis* and T-DNA transport by *Agrobacterium tumefaciens*, contact between cells induces a complex program of gene expression leading to DNA transport. Although the sequences for many conjugative elements have been completed and comparisons have revealed information on the evolution of conjugative elements, a study of the conjugative process has only been done in some depth for IncF, IncP, IncI, and the Ti plasmid of *A. tumefaciens* in gram-negative bacteria and for the pheromone-responsive system found for some plasmids in *E. faecalis*. Some information is available for the integration/excision process of conjugative transposons as well as the role of the *mob* genes in mobilizable plasmids. In addition, conjugation in *Streptomyces* has been studied in detail but is quite

different than that described and may use a DNA transport mechanism related to the process of DNA partition during cell division or septation in *Bacillus subtilis* (see Section V.B).

II. PHYSIOLOGICAL FACTORS

The level of transfer efficiency varies dramatically among the various systems. For derepressed or constitutively expressed systems such as F (IncFI) or RP4 (IncP α) maximal levels of mating (almost 100% conversion to plasmid-bearing status) are possible within 30 min. Plasmids undergoing fertility inhibition usually have a 100–1000-fold reduction in mating efficiency, whereas other plasmids, especially the smaller plasmids of gram-positive bacteria and conjugative transposons, mate at barely detectable levels in the best of circumstances. One critical factor that affects mating efficiency is temperature with very precise optimums usually being the rule. For instance, F and RP4 mate optimally at 37–42°C and IncH plasmids and the Ti plasmid at approximately 20–30°C. Other factors, such as oxygen levels, nutrient availability, and growth phase, contribute to mating efficiency. F⁺ cells in late stationary phase are known as F⁻ phenocopies because they are able to accept incoming F DNA and are not subject to surface or entry exclusion. Where information is available, conjugation appears to be maximal over a short temperature range in nutrient-rich environments with good aeration for aerobic organisms.

A. Liquid versus solid support

The ability of some conjugative systems to mate equally well in liquid media or on a solid support is one of the hallmarks of conjugation. Although all conjugative elements can mate well on a solid support, usually a filter placed on the surface of a pre-warmed nutrient agar plate, many transfer systems, including those of the IncF group and the pheromone-responsive plasmids of *Enterococcus*, mate very efficiently in liquid media. This difference can be traced to the nature of the mating pair formation process, with thick, flexible pili of gram-negative bacteria associated with systems that mate well in liquid media, whereas rigid pili, not usually seen attached to the cells (e.g. IncP α), require a solid support for efficient mating. The aggregation substance of *E. faecalis* allows high levels of transfer in liquid media but other gram-positive systems and conjugative transposons mate at low levels and absolutely require a solid support. In general, it appears that mating systems requiring a solid support

depend on collision between donor and recipient cells, whereas systems that mate well on either medium have a mechanism for initiating contact between freely swimming cells (thick, flexible pili, aggregation substance). Description of the media requirements for many gram-negative plasmid transfer systems is given in Bradley *et al.* (1980).

III. CONJUGATIVE ELEMENTS

Naturally occurring conjugative elements include plasmids, conjugative transposons, with either of these incorporated into the host chromosome to allow chromosome mobilization ability (CMA) resulting in high frequency of recombination (Hfr). Free plasmids can be divided into self-transmissible (Mpf plus Dtr genes) or mobilizable (Dtr or Mob genes) and can vary in size from a few kilobases to large plasmids of 100–500 kb.

A. Plasmids

In general, gram-negative transfer systems are approximately 20–35 kb in size and reside on plasmids from 60 to 500 kb, whereas mobilizable plasmids are less than 15 kb. The transfer or mobilization regions often represent half or more of the coding capability of the plasmid. Table 22.1 contains a list of selected plasmids and their characteristics, including their pilus type and mating medium preference. In non-filamentous gram-positive plasmids, the smaller plasmids (130 kb) usually have a requirement for a solid support during mating and mate at low levels, whereas the larger plasmids mate efficiently in liquid media and express genes for aggregate formation (e.g. *Enterococcus*, *Staphylococcus*, *Lactobacillus*, and *Bacillus thuriensis*). *Streptomyces* is able to mate at high frequency and has the added property of CMA. Each large, self-transmissible plasmid can supply the needed Mpf functions for many mobilizable plasmids. These mobilizable plasmids have been used to construct vectors which are maintained in the recipient cell or deliver their cargo of DNA via mobilization but are unable to replicate in the new host (suicide vectors). This has been a boon to the genetics of otherwise recalcitrant bacteria.

B. Chromosome mobilization

F undergoes integration into the chromosome via four transposable elements (IS2, IS3a and -b, and Tn1000) which either mediate cointegrate formation via a transposition event or more frequently undergo

TABLE 22.1 Selected conjugative/mobilizable plasmids and conjugative transposons

Mobile element	Size (kb)	Inc. group/pheromone	Copy no.	Mating surface/pilus type	Mating efficiency/host range
Gram-negative bacteria					
F	100	IncFI	1–2	Liquid/flexible (II)	High (derepressed)/narrow

homologous recombination between these sequences and similar elements on the chromosome. Once incorporated into the chromosome, the F replicon is suppressed by the chromosomal replication machinery allowing stable maintenance of the Hfr strain. Like F, which was found incorporated into the host chromosome, other examples of naturally occurring Hfr strains have been reported in the literature. Hfr strains have also been constructed using homologous gene segments shared by a plasmid and its host for mapping the host's genome. Since the advent of pulsed-field gel electrophoresis for mapping chromosomes and large-scale sequencing facilities, the utility of Hfr strains has waned. The procedure for using Hfr strains for chromosome mapping requires that F integrate near a locus with a few genetically defined markers. The direction of transfer of the chromosome and the time of entry of the markers into the recipient cell are functions of the position and orientation of F in the chromosome and its distance from each marker. By laboriously measuring the time of entry of each marker (e.g. antibiotic resistance and amino acid biosynthesis), which must be able to recombine into the recipient's chromosome in such a way as to announce its presence, a map of the chromosome can be generated. The process of mobilizing the entire *E. coli* chromosome takes approximately 90 min and markers that are distal from F *oriT* are transferred much less efficiently than those more proximally located, a process called the "gradient of transmission." The last portion of the chromosome to be transferred contains the F transfer region; consequently,

the recipient cells in an Hfr mating are seldom, if ever, converted to F⁺ (Hfr) status.

Another related property of F is imprecise excision out of the chromosome with adjoining chromosomal sequences being incorporated into the circular F element which are often large enough to encode complete operons. These elements are known as F' factors, such as *Flac*, *Fgal*, and *Fhis*.

C. Conjugative transposons

The first conjugative transposon was isolated from *E. faecalis* (Tn916; Table 22.1) in Clewell's lab in 1981 and expressed *tet* (M) (tetracycline) resistance. This element excises from the chromosome, circularizes into a non-replicative intermediate, and expresses functions for transfer to a wide range of recipient cell types at low frequency on solid surfaces (Salyers *et al.*, 1995). The enzymes responsible for excision and integration (Int and Xis) are related to the corresponding enzymes in lambda phage. The absence of a small repeated sequence flanking the conjugative transposon as well as a non-random site selection mechanism for integration suggests that these elements are evolutionarily more related to phage than true transposons. Excision of the element results in staggered ends which form a heteroduplex structure upon circularization. This heteroduplex is derived from flanking sequences in the chromosome ("coupling sequences"). Through mapping and sequencing the site of insertion and determining which end of the heteroduplex is inherited in the recipient, a model involving single-stranded DNA

transfer has been proposed. A second important group of conjugative transposons has been found in the anaerobic gram-negative genus *Bacteroides*. These elements are usually associated with antibiotic resistance (*tetX* and *erm*). The interesting property of increased transfer proficiency in the presence of tetracycline has been noted by Salyer's group.

Conjugative transposons demonstrate amazing versatility in mobilizing DNA. They can mobilize co-resident plasmids directly or form cointegrates with plasmids or the chromosome. They are also able to harbor other mobile elements such as transposons and integrons and move them between cells. In the case of *Bacteroides*, the conjugative transposons are able to excise and mobilize small nonconjugative, nonreplicative segments of DNA found in the chromosome called NBUs (non-replicating *Bacteroides* units). Although conjugative transposons have been identified in many genera of bacteria, especially in gram-positives, the details of the conjugation process remain obscure. An *oriT* region in Tn916 and a relaxase homolog in *Bacteroides* have been identified but the nature of the proteins involved in Mpf are unknown (Bonheyo *et al.*, 2001; Hinerfeld and Churchward, 2001).

IV. GRAM-NEGATIVE CONJUGATION

With the exception of *Bacteroides*, all gram-negative transfer systems encode a conjugative pilus (Type II) which is essential for mating pair formation and DNA transport (Fig. 22.1). In thick, flexible pilus mating

systems, the pili are easily found attached to the donor cell and examples of the pilus mediating contact between the donor and recipient cell are easy to visualize in the electron microscope. In the case of rigid pilus mating systems, pili are rarely seen attached to cells but are seen as bundles of pili accumulating in the medium. Although there is considerable homology between all the transfer systems examined to date within the gram-negative group of organisms, two broad classes can be identified. These include IncF-like and IncP-like plasmids, which also represent mating systems categorized by their ability to mate in liquid versus solid media or systems encoding thick, flexible pili versus rigid pili. Some of the gene products in IncI transfer systems are distantly related to those of IncP, however the remaining gene products are distinct and have homology to the Icm/Dot proteins of *Legionella pneumophila*. All conjugative systems identified to date have a relaxase (Tra_{Fp}/Nik_I), and a protein that energizes DNA transport (TraD_F/TraG_p/TrbC_I) as well as a protein that is involved in pilus assembly (TraC_F/TrbE_p/TraU_I). F-like systems have the characteristic Mps genes, *traG* and *traN*, whereas P-like systems all have a TrbB homologue. IncI systems also have a TrbB (TraJ_I) homologue but also encode a second type IV pilus (*pil*) used in Mps. The principal systems studied to date include F (Frost *et al.*, 1994); P-like systems include IncP plasmids RP4 and R751 (Pansegrau *et al.*, 1994); ColIb-P9 (IncI, Komano *et al.*, 2000), R27 (IncHI1, Lawley *et al.*, 2002) which has features of F and P systems; pCU1 and pKM101 (IncN; Pohlman *et al.*, 1994), R388 (IncW; Gomis-Ruth *et al.*, 2001), and the Ti plasmid of *A. tumefaciens* (Christie and Vogel, 2000) (Table 22.2).

leader peptidase (LepB) and the pilin subunit is acetylated at the N terminus by TraX. Transposon insertion studies have revealed that mature pilin is oriented as two α -helical transmembrane segments within the inner membrane, with the N and C termini facing the periplasm. Assembly by the TraL, -E, -K, -B, -V, -C, -W, -U, -F, -H, and -G and TrbC proteins results in the subunits oriented within the fiber such that the acetylated N terminus is buried within the structure and the C terminus is exposed on the sides. The pilus appears to assemble at its base rather than at the tip based on evidence using the slowly assembled pili expressed by the IncHI1 plasmid R27.

The RP4 pilin subunit is expressed as a 15-kDa prepilin polypeptide (*trbC* in Tra2), which is processed three times to give a 78 aa cyclic peptide. The cleavage reactions at the N and C termini are undertaken by LepB (N terminus) and an unidentified host peptidase as well as by a pilin-specific LepB homolog, TraF, expressed by RP4, which cleaves a further four amino acids from the C terminus and cyclizes the subunit by joining the N and C termini (Eisenbrandt *et al.*, 2000). The RP4 transfer region is separated into two parts, Tra1 and -2. In addition to *traF* of Tra1, the essential genes *trbB-L* of Tra2 are required for pilus assembly, with TrbK being involved in entry exclusion. The structure of TrbB has been determined and is a soluble, double ring-like structure which utilizes ATP during pilus synthesis and presumably, DNA transfer. A homolog of TraX is present in RP4 (TraP), although its substrate and function are unknown. Cyclic pilins have been identified in the Vir system of the Ti plasmid and are suspected in a number of other systems that carry a TraF_p homologue.

2. Phage attachment

Conjugative pili act as the primary receptor for a wide range of bacteriophages (Frost, 1993). These phages can be divided broadly into those that bind to the pilus tip and those that bind to the sides of the pilus. The structure of the phages includes the single-stranded DNA filamentous phages, the small isometric RNA phages, and the complex double-stranded DNA tailed phages which usually attach near the pilus tip. The filamentous phages specific for F-like pili (Ff phages; M13, f1, and fd) attach via a defined region of the pilin attachment protein to an unknown receptor at the pilus tip. RNA phages such as R17 and Q β , which belong to different phage groups, bind to specific residues in F pilin exposed on the pilus sides. For RP4 (IncP α), the filamentous phage Pf3 binds to the sides of the pilus as does the RNA phage PRR1. Tailed phages such as PRD1 and PR4 bind to the pilus

tip and have a broad host range, including cells bearing IncP, -W, -N, and -I plasmids.

Although the pilus is required for initial attachment, the transfer region is not necessarily required for phage penetration or growth. The Ff phages are thought to contact the cell surface via the process of pilus retraction where they interact with the TolA protein and penetrate the cell via the TolQRA pathway. RNA phages R17 and Q β have differing requirements for the TraD protein, which energizes the transport of nucleic acid through the conjugation pore, suggesting that R17 is imported via the F transfer machinery, whereas Q β is taken up by another pathway.

3. Role in conjugation

The role of the pilus in conjugation has been controversial. It clearly has a role in Mpf, but whether it has a role in initiating DNA transfer or is part of the transfer apparatus has been difficult to determine genetically. Mutations that affect pilus formation block Mpf and DNA transfer. Mutations that affect mating pair stabilization (TraN and -G) allow the initial contacts to form between cells via the pilus and also allow the initiation of DNA synthesis in the donor cell but block DNA transport into the recipient cell. Although indirect, this is the best evidence that the pilus is involved in the signaling process and the Mps genes are involved in transport possibly by forming the conjugation pore. Whether pore formation also requires an intact pilus remains unknown. Other experiments in which donor and recipient cells were not allowed to establish cell-to-cell contact suggested that mating was possible through the extended pilus, and the homology between the pilus assembly genes and protein transport systems also argues for a role for the pilus in DNA transfer.

B. Mating pair formation

The pilus is thought to identify a receptor on the recipient cell surface, which triggers retraction of the pilus into the donor cell, although the route of the pilin subunits in this process is unknown. Pilus outgrowth is thought to require energy, whereas retraction occurs by default in the absence of assembly. Thus, factors that negatively affect cell metabolism (temperature, poisons, and carbon source) cause retraction. Whether pilus outgrowth and retraction are ongoing processes or whether binding of recipient cells or phage trigger retraction is unknown.

Early studies to identify mutations in the recipient cell that affected conjugation (Con⁻) revealed that various components of the heptose-containing inner

core of the lipopolysaccharide (LPS) were generally important in Mpf, whereas OmpA was required for efficient conjugation by the F transfer system. The F-like systems were each affected by different mutations in the *rfa* (now *waa*) locus in the recipient cell, whereas the IncH plasmids seemed to recognize a generalized negative charge on the recipient cell surface. The requirement for OmpA by F as well as for specific side chains in the LPS appears to be a function of the outer membrane protein TraN, whereas the idea that the pilus recognizes negatively charged moieties non-specifically remains a possibility. A second protein identified in F that is involved in Mps is TraG. Mutations in *traG* can be categorized into two classes with ones near the 5' end affecting pilus formation and others affecting mating pair stabilization (Mps) in the 3' portion of the gene.

An interesting variation on Mps has been identified for the IncI1 transfer systems (R64 and Collb-P9) which express two types of pili: thin flexible pili which are required for Mps and thick rigid pili that are required for DNA transfer. Research on the thin pili of R64 by Komano's group has revealed that they are composed of type IV pilin (similar to the pili found in pathogens such as *Neisseria gonorrhoeae*) of 15 kDa (*pilS*). These pili have a protein at their tip (*pilV*) whose gene undergoes rearrangement via site-specific recombination by the *rci* gene product to form seven possible fusion proteins, each recognizing a specific LPS structure (e.g. *pilVA'*). Whether these pili retract in order to bring the donor and recipient cells together is unknown, however, this is a general feature of type IV pili. Aside from these two cases (F and R64 thin pili), little is known about Mpf in other gram-negative systems.

1. Surface/entry exclusion

Surface or entry exclusion reduces redundant transfer between equivalent donor cells. Such transfer is thought to be deleterious to the donor cell and is exemplified by the phenomenon of lethal zygosis which occurs when a high ratio of Hfr donor to recipient cells is used. Multiple matings with a single recipient cell result in its death because of severe membrane and peptidoglycan damage as well as induction of the SOS response resulting from the influx of a large amount of single-stranded DNA. The surface exclusion genes were first identified as the *ilz* locus (immunity to lethal zygosis).

The mechanism of entry or surface exclusion is unknown, although some sort of exclusion mechanism has usually been found to be associated with the transfer systems studied to date. One exception is the

conjugative transposons, which transfer at such low frequency that redundant transfer might not be a factor. Surface exclusion in the F system involves TraT, a lipoprotein found in the outer membrane of potential recipient cells, that forms a pentameric structure and blocks mating pair stabilization. Whether it interacts with the pilus or another component of the F transfer system is unknown. The TraS protein of F is an inner-membrane protein in the recipient cell which blocks the signal that DNA transfer from the donor cell should begin and is thus associated with the property of entry exclusion. TraS has been shown to exhibit plasmid specificity for the TraG protein from the same mating system expressed in the donor cell. TrbK, a lipoprotein found in the inner membrane of RP4-containing cells, is also thought to cause entry exclusion.

C. DNA metabolism

1. Organization of *oriT*

In gram-negative transfer systems, the origin of transfer (*oriT*) can be ~40–500 bp in length and contains intrinsic bends and direct and inverted repeats which bind the proteins involved in DNA transfer. The *nic* site, which is a strand- and sequence-specific cleavage site, is cleaved and religated by the relaxase. In most cases, the relaxase requires an auxiliary protein(s) which directs the relaxase to the *nic* site and ensures the specificity of the reaction. The sequences of the *nic* sites identified to date reveal five possible sequences represented by IncF, -P, and -Q and certain gram-positive plasmids such as pMV1158. In addition, there is usually a protein that binds to multiple sites within *oriT* forming a higher order structure in the DNA which is essential for the process. This protein also appears to have a function in anchoring the relaxosome to the transport machinery (Lanka and Wilkins, 1995; Zechner *et al.*, 2000).

2. Mechanism of DNA transfer

After mating pair formation, a signal is generated that converts the relaxosome from the cleavage/religation mode to one in which unwinding of the DNA is coupled to transport through the conjugation pore in an ATP-dependent manner. The transfer rate is ~750 nucleotides per second, with the F plasmid (100 kb) transferred in approximately 3 min.

In IncF plasmids, TraI is the relaxase/helicase enzyme which binds to a site near *nic* and generates an equilibrium between cleavage and religation. This reaction requires supercoiled template DNA and Mg²⁺ as well as the auxiliary proteins F TraY and host

integration host factor (IHF) *in vitro*. The signal that triggers the helicase activity of TraI, which is essential for DNA transfer, is unknown, as is the function of TraI* produced by a translational restart in the *traI* mRNA. TraY binds near *nic*, whereas TraM binds to multiple sites, in conjunction with IHF, to form a nucleoprotein complex required for transfer to be initiated. TraM also binds to the protein that energizes transport, TraD, which is an inner-membrane protein that utilizes ATP probably via its two NTP binding domains. The crystal structure of the soluble domain of TrwB, a TraD_F and TraG_P homolog, has revealed a hexameric ring reminiscent of packaging proteins of phage and the F'-ATPase.

In RP4, a similar arrangement of proteins at *oriT* exists except that there is no role for the host protein, IHF. The relaxase protein, called TraI, cleaves at *nic* as a complex with TraJ, whereas TraH stabilizes the TraI, J complex. TraK binds and bends the DNA at *oriT* to form the nucleosome-like structure thought to be needed to initiate DNA replication.

In all cases, the 5' phosphate generated by the cleavage reaction remains covalently bound to the relaxase enzyme via a tyrosine residue which is similar to the initiation of replication by the rolling circle mechanism in some phage and plasmid replicons. The DNA is transferred in a 5' to 3' direction, with the first genes to enter the recipient cell called the leading region. Transfer seems to be a precise process with termination of transfer after one copy of the plasmid has been delivered to the recipient cell. A sequence in *oriT*, near *nic*, is important for termination by the relaxase in a religation reaction. The DNA is released into the recipient cell and both strands are replicated in a manner dependent on the PolIII enzyme using discontinuous synthesis in the recipient and continuous synthesis either from the free 3' end at *nic* or from an RNA primer in the donor. Although synthesis and transport are coupled in conjugation, DNA synthesis does not drive, nor is it required, for DNA transfer.

In RP4, the transport of a primase protein, Pri (*traC* encoded in Tra1), or Sog by IncI plasmids, has been demonstrated to occur simultaneously with the transport of the DNA, with hundreds of copies being transferred to the recipient cell. This protein appears to initiate DNA synthesis in the recipient cell via primer formation, although it is not essential for conjugation. In F, no primase is transferred and DNA synthesis is thought to begin via a mechanism utilizing *ssi* sites for single-stranded initiation.

3. Leading region expression

The first genes to enter the recipient cell in the leading region include genes for preventing restriction of the

incoming DNA as well as the SOS response (*psi*) and for plasmid maintenance via poison-antidote systems such as CcdAB and Flm in F, Hok/Sok in R1, and Kil/Kor in RP4. One gene that is highly conserved in the leading region of conjugative plasmids is *ssb*, a single-stranded DNA binding protein that is not essential to the process. These genes are transcribed from single-stranded DNA promoters that ensure expression prior to the completion of replication. Another interesting but nonessential gene is *orf169* in F or TrbN in RP4 which is related to lytic transglycosylases such as lysozyme. Perhaps this gene, which is the first to enter the recipient cell during F transfer, has a role in establishing a new transferosome in the recipient cell, especially in strains of bacteria in the natural environment which might require a transglycosylase to rearrange the peptidoglycan in preparation for pilus assembly and DNA transfer.

D. Regulation

The regulation of the genes involved in conjugation has been extensively studied in F, RP4, and Ti (see Section VII) and in gram-positive conjugation, but there is little information on other systems. The regulation of F transfer gene expression depends on both host and plasmid-encoded factors, whereas the regulation of RP4 appears to be independent of the host. Also, F is unusual in that there is no evidence for coregulation of transfer and replication, a salient feature of other conjugation systems.

In F, there are three main transcripts encoding *traM*, *traJ* (the positive regulator of transfer operon expression), and *traY-I* (33 kb). The P_{Y-I} promoter is controlled by a consortium of proteins, including the essential TraJ protein; TraY, the first gene in the operon; and IHF and SfrA (also known as ArcA) encoded by the host. TraY also controls *traM* expression from two promoters which are autoregulated by TraM. The translation of the *traJ* mRNA is controlled by an antisense RNA FinP which requires an RNA binding protein FinO for activity (fertility inhibition; see Section IV.D.1). Certain mutations in *cpxA* also affect TraJ stability probably via an indirect mechanism involving upregulation of factors that respond to stress applied externally to the cell.

In RP4, transfer is tied very closely to replication with the main replication promoter for TrfA divergently oriented and overlapping with the first of two promoters for the Tra2 transfer region, P_{trbA} and P_{trbB}. In this system, the *trfA* promoter is activated first in the transconjugant, promoting plasmid replication. The P_{trbB} promoter and the promoters in Tra1, which express the genes for Dtr, are also activated in order to establish a new transferosome. Eventually, the main

global regulators KorA and KorB repress expression from these promoters and allow transcription from P_{trbA} which maintains the level of Tra2 proteins in the donor cell. TrbA is a global regulator that represses P_{trbB} and the three promoters in Tra1 encoding the genes for Dtr. Thus, conjugation leads to a burst of transcription that establishes the plasmid in the new donor cell followed by transcription from either the *trfA* or the *trbA* promoters during vegetative growth.

1. Fertility inhibition

Fertility inhibition (Fin) is a wide-spread phenomenon which limits the transfer of competing plasmids coexistent in a single cell. The fertility inhibition systems of F-like plasmids (R factors) repress F and also autoregulate the expression of their own transfer regions. These systems have two components, the antisense RNA FinP and the RNA binding protein, FinO, which together prevent translation of the *traJ* mRNA, with TraJ being the positive regulator of the P_{YI} promoter. FinO protects FinP antisense RNA from degradation by the host ribonuclease, RNase E, allowing the FinP concentration to increase sufficiently to block *traJ* mRNA translation. Although *finP* is plasmid-specific, *finO* is not, and can be supplied from many F-like plasmids. This is the basis of the fi^+ phenotype noted in the 1960s for various R factors. F lacks FinO since *finO* is interrupted by an IS3 element and consequently is constitutively de-repressed for transfer.

In F-like plasmids (FinOP⁺), 0.1–1% of a repressed cell population expresses pili. If conjugation is initiated, the transconjugant is capable of high frequency of transfer (HFT) for approximately six generations until fertility inhibition by FinOP sets in. This phenomenon, in addition to surface/entry exclusion which ensure transfer only to recipient cells, contributes to the epidemic spread and stable maintenance of a plasmid in a natural population of bacteria.

Other Fin systems are specified by one plasmid and are directed against another. For instance, F encodes PifC, which blocks RP4 transfer, whereas RP4 encodes the Fiw system, which blocks the transfer of coexistent IncW plasmids. Each system has a unique mechanism which has made the study of Fin systems more difficult and has tended to downplay the importance of this phenomenon in the control of the dissemination of plasmids in natural populations.

V. GRAM-POSITIVE CONJUGATION

Conjugative elements in non-filamentous gram-positive bacteria can be subdivided into three groups: (i) small

plasmids (130 kb), usually associated with MLS resistance, exhibit moderate transfer efficiency on solid surfaces over a broad host range (pAM β 1 and pIP501); (ii) large plasmids (+60 kb), which mate efficiently in liquid media over a narrow host range and undergo clumping or cell aggregate formation (pAD1 and pCF10 in *Enterococcus*; pSK41 and PGO1 in *S. aureus*); and (iii) conjugative transposons.

There is no evidence for pili in gram-positive conjugation. In the few systems studied in detail, detection of a recipient cell results in expression of an aggregation substance (AS, Agg, or Clu) which covers the surface of the donor cell and results in the formation of mating aggregates which are visible to the naked eye. This “fuzz” is the result of a complex pattern of gene expression which has been studied in detail only rarely, mostly in the large plasmids of *E. faecalis*. This group of plasmids responds to pheromones expressed by the recipient cell, whereas the signal that triggers mating aggregate formation in other systems is poorly understood. Plasmids in *S. aureus* produce pheromones that trigger transfer by *E. faecalis*, suggesting a mechanism to broaden the host range for plasmids of the latter organism.

A. *Enterococcus faecalis*

The first conjugative plasmid identified in gram-positive bacteria was pAD1, which carried a hemolysin/bacteriocin determinant responsible for increased virulence and which caused clumping or aggregation 30 min after the addition of plasmid-free cells (Dunny and Leonard, 1997). Later it was shown that aggregation and subsequent plasmid transfer were induced by pheromones produced by the recipient cell and released into the medium. These pheromones are hydrophobic peptides of seven or eight amino acids with a single hydroxyamino acid. Each recipient cell releases several pheromones, with plasmids from a particular incompatibility group recognizing a specific pheromone in which specificity resides in the N terminus of the peptide. In addition to their role in conjugation, the function of these pheromones is unknown, as is their source. Once the plasmid has become established in the transconjugant, expression of the pheromone is repressed by preventing its synthesis in or release from, the donor cell. Picomolar amounts of pheromone added to donor cultures can induce the expression of the transfer genes. Usually the concentration is approximately 1–10 nM and a slight increase in pheromone levels is sufficient to induce clumping. Pheromones are named after the transfer system that recognizes them; thus, pAD1 recognizes cAD1 and produces iAD1, an

inhibitory peptide that blocks accidental induction of transfer.

The pheromone is recognized by a plasmid-encoded protein and imported into the cell via the host Opp system (oligopeptide permease). In pAD1, it binds to a repressor, TraA, inactivating it and allowing transcription of TraE1, a positive regulator required for induction of transfer gene expression. In pCF10, the pheromone cCF10 causes anti-termination of transcription of the *prg* genes (pheromone responsive gene) generating the 530 nt RNA Q_L and the mRNA for aggregation substance and transfer proteins. The Q_L RNA, in conjunction with the pheromone, associates with the ribosome causing preferential translation of the transfer genes. In either case, transcription of the aggregation substance (AS or Asa1 for pAD1 and Asc10 for pCF10) ensues, and this substance is deposited asymmetrically on the surface of the cell until the cell surface is covered. This binds to the binding substance (BS; lipoteichoic acid) on the recipient cell to give the mating aggregates so characteristic of conjugation. Interestingly, both AS and BS have been associated with increased virulence in a rabbit endocarditis model, with AS having RGD motifs (arginine-glycine-aspartic acid) which are known to promote binding to the integrin family of cell surface proteins.

Once the pCF10 transferosome is established in the transconjugant, a cytoplasmic membrane protein binds pheromone and prevents its release. The inhibitory peptide, iCF10, is synthesized from a shorter version of Q_L called Q_S . A surface exclusion protein, Sea1 or Sec10 (for pAD1 or pCF10, respectively), is also expressed to reduce aggregation between donor cells and provides a second level of control to prevent redundant mating between plasmid-bearing cells.

There also seems to be a close relationship between replication and transfer in these plasmids, with the replication protein PrgW embedded within a region that negatively regulates transfer in pCF10. The replication protein also appears to have a requirement for pheromone that is not understood. Similarly, the *oriT* for pAD1 is within the *rep* gene for plasmid replication initiation.

B. *Streptomyces*

The transfer systems found on conjugative plasmids in the large genus *Streptomyces* differ significantly from those of both non-filamentous, gram-positive bacteria and gram-negative systems in that there is only a single essential transfer protein and no evidence for a relaxase or *nic* site has been found. *Streptomyces* are a medically important source of

antibiotics and other therapeutic compounds and are thought to be a major reservoir for antibiotic resistance mechanisms which protect these bacteria from the arsenal of antibiotics they produce.

The conjugative plasmids of *Streptomyces* range in size and structure from the circular 9-kb plasmid pIJ101 to the large linear plasmid SCP1 (350 kb). The phenomenon of conjugation in this genus was first identified because of the ability of certain integrating plasmids to mobilize chromosomes (CMA). One such plasmid, SLP1 (17 kb), excises and integrates at the 3' end of an essential tRNA^{Tyr} gene in *S. lividans*, with tRNA genes providing the loci for integration of many phage and plasmids.

Streptomyces are soil microorganisms that undergo a complex differentiation program whereby spores germinate and form substrate mycelia that penetrate into the support surface followed by the erection of aerial hyphae which are multinucleate mycelia. These mycelia eventually septate and form spores. As the cells enter the hyphal stage, they begin to produce the array of secondary metabolites characteristic of the organism and also enter a phase in which they are competent for conjugation between substrate mycelia or mycelia and other organisms such as *E. coli*.

The intermycelial transfer of a plasmid requires one essential protein (e.g. Tra in pIJ101) which has homology to the cell division protein FtsK in *E. coli* and SpoIIIE which is located at the asymmetric septum of sporulating *B. subtilis* cells and ensures that a copy of the chromosome enters the forespore. Since no relaxase protein has been found associated with pIJ101, it is tempting to speculate that this might be a conjugation system closely related to partitioning mechanisms involving double-stranded DNA.

Once the DNA has been transferred to one compartment of a long mycelium, the plasmid is distributed to all compartments by the *tra* and the *spd* gene products. This process slows the growth rate of the cell, and areas in which plasmids are being spread via inter- and intramycelial transfer form "pocks" of more slowly growing cells which resemble plaques on a phage titer plate. This phenomenon has been useful in identifying cells containing conjugative plasmids.

VI. MOBILIZATION

Mobilization is a widespread phenomenon whereby a smaller plasmid encoding its own *nic* site and Dtr genes (*mob*) utilizes the transport machinery of a usually larger plasmid to effect its own transfer. Many

plasmids can be mobilized by plasmids from many Inc groups. For instance, CoIE1 can be mobilized by plasmids from IncF, -P, and -I groups and less effectively and with different requirements by IncW plasmids. The Mob proteins of CoIE1 consist of MbeA (relaxase) and MbeB and -C, which aid in relaxosome formation. MbeD has an entry-exclusion function. In the vector pBR322, derived from CoIE1, the *mob* genes are deleted and only an *oriT* region for IncP plasmid mobilization remains. Although CoIE1 requires TraD from F for mobilization, the closely related plasmid CloDF13 supplies its own TraD-like protein, a difference which is commonly seen among mobilizable plasmids.

The most remarkable mobilizable plasmid is RSF1010 and its relatives (~8.6kb in size) from the IncQ group. These plasmids are mobilized very efficiently by plasmids from the IncP group into an extremely broad group of recipients, including bacteria, yeast, and plants. This plasmid encodes three Mob proteins, with MobA being the relaxase. Like CoIE1, it requires the TraG protein of RP4 for efficient mobilization but it is only efficiently mobilized by F TraD if a C-terminal deletion is made. The *oriT* region is a mere 38bp in size and is homologous to *oriT* regions in plasmids from gram-positive bacteria, all of which use a rolling circle mechanism during transfer. RSF1010 can be mobilized into plants and between agrobacteria by the *vir* region (not *tra*; see Section VII) and between strains of *Legionella* using the virulence determinants encoded by the *dot* and *icm* loci involved in macrophage killing (see Section VIII).

Small gram-positive plasmids are also mobilizable by self-transmissible plasmids but less is known about them. The utility of conjugative transposons as genetic tools in gram-positives has overshadowed interest in these plasmids, which tend to be mobilized at low frequencies over long time periods. One plasmid, which replicates and transfers via the rolling circle mechanism using different origins, is pMV1158. It encodes a relaxase (MobM) which cleaves at a *nic* sequence unique to a group of mobilizable plasmids found in gram-positive bacteria representing the fourth class of *nic* sequences.

VII. TRANSFER TO PLANTS

The phenomenon of DNA transfer from the bacterium *A. tumefaciens* to plant cells has features of both gram-negative (pilus expression) and gram-positive (induction of *tra* gene expression) and has been dealt with here separately (Fig. 22.3). *Agrobacterium tumefaciens* carrying large conjugative plasmids such as Ti

FIGURE 22.3 The signaling pathway used to stimulate T-DNA complex transfer to the plant nucleus and Ti conjugative transfer between agrobacteria. Wounded plant tissue releases phenolics (acetosyringone) and sugars (1) that are detected by the VirA, G two-component regulatory system (2). This induces expression of the *vir* genes which transports the T-DNA to the plant nucleus (3). The T-DNA is incorporated into the plant genome and produces the phytohormones auxin (indoleacetic acid) and cytokinin (4) which trigger tumorigenic growth of the plant tissue. The plant also produces opines (5), whose synthesis is encoded on the T-DNA. These unusual amino acids serve as a food source for *Agrobacterium* and also result in the induction of synthesis (6) of the conjugation factor, *N*- β -oxo-octanoyl-homoserine lactone (AAI; 7). AAI allows "quorum sensing," which determines cell density with respect to Ti-plasmid-bearing cells resulting in conjugative transfer to other agrobacteria (8).

(tumor-inducing) or Ri (root-inducing) of +200 kb in size cause crown gall disease in plants whereby they induce the formation of tumors at the site of infection. The Ti plasmid encodes a sensor-response regulator system, VirA and VirG, respectively, which in conjunction with ChvE, a chromosomally-encoded periplasmic sugar binding protein, process signals from wounded plant tissue. The phospho-transfer reaction from VirA to VirG induces gene expression from the *virA*, -B, -D, -E, and -G operons on the Ti plasmid. In addition, the *virC*, -F, and -H operons are induced but these operons express nonessential gene products that affect host range or the degree of virulence. The signals generated by the plant include phenolic compounds, simple sugars, and decreased pH or phosphate content.

The *virB* region encodes 11 proteins which are homologous to the gene products in the Tra2 region of RP4 and distantly related to the gene products of F. They encode the gene for prepropilin (VirB2), which is processed to cyclic pilin via a mechanism similar to

that for RP4 pilin. A potential peptidase, homologous to TraF in RP4, has been identified (VirF) but its role has not been proven. The assembly of the VirB pilus is very temperature dependent, with an optimum of 19°C and a corresponding optimum for the transfer process. Considerable work has been done to understand the organization of the Vir proteins in the conjugative pore. In general, there appears to be a set of proteins that forms pores in the inner (VirB6, 8, and 10) and outer (VirB7, and 9) membranes with VirB2, 3, 4 and 5 involved in pilus assembly and associated with these complexes (Das and Xie, 2000).

The specific segment of single-stranded DNA that is transferred to the plant nucleus is called the T-DNA and can be characterized by the right (RB) and left (LB) borders which are direct repeats of 25 bp. The T-DNA of nopaline-producing Ti plasmids is approximately 23 kb in length and contains genes for plant hormone expression (13 kb), a central region of unknown function, and a region for opine (nopaline) biosynthesis (~7 kb). The relaxase, VirD2, in conjunction with VirD1, which is similar to RP4 TraJ, cleaves at RB and subsequently LB in a TraI-like manner and remains attached to the 5' end. VirC1, which binds to an "overdrive" sequence near the RB, and VirC2 of certain Ti plasmids enhance T-intermediate formation. Unlike other transfer systems, many copies of the T-DNA segment accumulate in the cytoplasm suggesting replacement replication is important in this system. The accumulation of T-DNA strands has been puzzling but might represent a strategy by the bacterium to ensure infection of the larger, more complex plant cell.

The DNA in the VirD2-T-DNA complex (T-complex) is coated with the single-stranded DNA binding protein, VirE2, in preparation for transport through a conjugation pore composed of the VirB proteins (VirB2-VirB11). These proteins are very homologous to the Tra2 gene products for pilus synthesis in RP4 (Christie and Vogel, 2000), again suggesting the importance of the pilus to DNA transport. One of the Vir proteins, VirB1, which is nonessential, resembles the transglycosylase of F (Orf169) and RP4 (TrbN), whereas a truncated version of VirB1 (VirB1*) is excreted into the rhizosphere and mediates adhesion between the bacterium at the site of transfer and the plant. The process is energized by an RP4 TraG homolog, VirD4, which has NTP binding motifs that are required for its activity. Once the T-complex has entered the plant cytoplasm, the DNA is transported to the nucleus via nuclear localization signals on the VirE2 and VirD2 proteins. The T-DNA is randomly integrated into the plant genome whereupon it begins to elicit signals for plant hormone production resulting

in tumor formation. The T-DNA encodes for the synthesis of auxin (indoleacetic acid) and cytokinin isopentenyl adenosine, plant hormones that elicit uncontrolled growth at the site of infection. The bacteria derive nutrients from the tumor by the devious method of opine (unusual amino acid) production encoded by the T-DNA. Opines can be classified into approximately nine different types of compounds, including octopine, nopaline, and agrocinopine, with up to three different opines being encoded by a particular T-DNA. Thus, Ti plasmids are often referred to as octopine- or nopaline-type plasmids, for instance, depending on the opine they specify. The opines are excreted from the plant and taken up by the *A. tumefaciens* bacteria encoding a region on the Ti plasmid involved in opine utilization. The genes for opine catabolism (e.g. *occ* for octopine catabolism) match the genes for the synthesis of that class of opines on the T-DNA.

An interesting aspect of Ti plasmid biology is the induction of conjugative transfer between agrobacterial cells in response to the presence of opines. The genes for this process (*tra*) are distinct from the genes for T-DNA transfer (*vir*) and encode a transfer region with homology to RP4 as well as the *vir* region.

Conjugative transfer by Ti has a narrow host range, limited to the genus of *Agrobacterium*. However, the host range can be extended to *E. coli* if an appropriate replicon is supplied, suggesting that it is plasmid maintenance and not conjugative functions that affect host range.

The process of inducing conjugative transfer in these bacteria is unique and fascinating (Fuqua *et al.*, 1996). Initially, there is a low level uptake of opines which activates the regulatory protein OccR in octopine-type plasmids and inactivates the repressor protein AccR in nopaline-type plasmids such as pTiC58. This leads to increased expression of the *tra* and opine utilization genes by activation of TraR. TraI (not to be confused with the relaxase proteins of F and RP4 plasmids) is a LuxI homolog which synthesizes a signalling compound, *N*- β -oxo-octanoyl-homoserine lactone (*Agrobacterium* autoinducer; AAI) belonging to a diverse class of homoserine lactone-like compounds involved in quorum sensing or gene activation in response to cell density (Fig. 22.3). TraR is a LuxR-like regulatory protein which detects increased levels of AAI and induces transfer gene expression to maximal levels. The result is the dissemination of the genes for opine utilization among the agrobacteria in the rhizosphere. Thus, the system demonstrates a certain degree of chauvinistic behavior since the original colonizer of the plant cell shares its good fortune with its neighbors who then out-compete other bacteria in the rhizosphere.

VIII. EVOLUTIONARY RELATIONSHIPS

With the advent of high-throughput sequencing and easily available databases, comparison of gene sequences has become routine. Considering that the mechanism for conjugation varies surprisingly little among the systems described previously, the high degree of relatedness of these systems with one another is expected (Table 22.2). However, the remarkable finding that there is homology between conjugative systems and transport mechanisms for many toxins and virulence determinants as well as transformation systems in naturally competent bacteria has generated increased interest in conjugation resulting in its inclusion in Type IV secretion systems. There is almost gene-for-gene homology between the transport system for pertussis toxin of *Bordetella pertussis* (*ptl*) and the *virB* region of the Ti plasmid, which is in turn, homologous to the genes for pilus synthesis in IncN, -P, and -W transfer systems and is distantly related to those of F-like plasmids. Recently, five *vir* homologs (*VirB4*, -9, -10, and -11 and *VirD4*) have been found in the *cag* pathogenicity island of *Helicobacter pylori* while a separate type IV genomic island is responsible for natural transformation in this organism. Also, some of the Dot/Icm proteins involved in the pathogenesis of *Legionella pneumophila*, which can mobilize RSF1010, are homologous to genes in the Tra region of the Inc11 plasmid R64 and the Tra2 region of RP4. Other prominent type IV systems include DNA excretion in *Neisseria gonorrhoeae* which closely resembles F (Dillard, personal communication) as well as type IV-like genomic islands in *Rickettsia prowazekii* and *Brucella abortus* (Christie and Vogel, 2000). Analysis of the genome sequences in the databases reveals many type IV-like sequences, suggesting that this is a widespread transport mechanism. The array of substrates that can be transported by type IV systems is impressive, as is their ability to transport these substrates in either direction. This suggests that a primordial transport system, perhaps derived from a filamentous phage, has been adapted to many uses.

IX. CONJUGATION IN NATURAL ENVIRONMENTS

Although the process of conjugation is thought to be relevant to the adaptation of organisms to environmental conditions such as the acquisition of antibiotic resistance under continuous pressure for selection, there is much to be learned about the process in

nature (Davison, 1999; Paul, 1999). Conjugation can be demonstrated in the gut of animals, biofilms, soil, aquatic environments including wastewater, on the surface of plants and animals, etc. However, the level of transfer is usually very low. Most experiments have utilized common lab strains and plasmids, which are good model systems for study, but might be irrelevant in nature. Considering the diversity of bacterial species, their vast numbers, and the time scale for their evolution, we have only scratched the surface of this phenomenon in the natural environment. However, studies on "domesticated" lab strains and plasmids have allowed predictions about the conditions that favor transfer. Most conjugative systems require actively growing cells in exponential phase and have a fairly precise temperature optimum. The majority of systems studied to date mate more efficiently on solid media. Those systems that mate efficiently in liquid media seem to be found in enteric bacteria and might be associated with diseases which are transmitted via the water supply. More information is required on the natural hosts for conjugative elements and their contribution to the evolution of these elements in an ecological niche. In addition, the most likely route of transmission, which appears to involve many intermediate organisms, is usually impossible to predict or detect because of the complexity of the system and the unknown role of non-culturable organisms in this process. Thus, we can isolate a plasmid from its environment and we can find evidence for its transfer to a new species, but we cannot, at this time, follow the plasmid as it makes its way in the world.

Crystalline bacterial cell surface layers (S layers)

Uwe B. Sleytr and Paul Messner

Centre for Ultrastructure Research and Ludwig Boltzmann Institute for Molecular Nanotechnology,
University of Agricultural Sciences

GLOSSARY

crystalline surface layers (S layers) In prokaryotic organisms, composed of protein or glycoprotein subunits.

S-layer (glyco)proteins Present as monomolecular arrays on surfaces of archaea and bacteria.

two-dimensional protein crystals Regular arrays of (glyco)proteins present as outermost envelope component in many prokaryotic organisms.

Surface Layers (S layers) are cell envelope components on prokaryotic cells consisting of two-dimensional crystalline arrays of (glyco)protein subunits. S layers have been observed in species of nearly every taxonomical group of walled bacteria and represent an almost universal feature of archaeal envelopes. As porous crystalline arrays covering the cell surface completely, S layers have the potential to function: (i) as protective coats, molecular sieves, and molecule and ion traps; (ii) as structures involved in cell adhesion and surface recognition, and (iii) in archaea, which possess S layers as exclusive wall components, as a framework that determines and maintains cell shape.

(S layers) are now recognized as common features of both bacteria and archaea.

Most of the presently known S layers are composed of a single (glyco)protein species endowed with the ability to assemble into two-dimensional arrays on the supporting envelope layer. S layers, as porous crystalline membranes completely covering the cell surface, can apparently provide the microorganisms with a selective advantage by functioning as protective coats, molecular sieves, molecule and ion traps, and as a structure involved in cell adhesion and surface recognition. In those archaea that possess S layers as exclusive envelope components outside the cytoplasmic membrane, the crystalline arrays act as a framework that determines and maintains the cell shape. They may also aid in cell division. In pathogenic organisms S layers have been identified as virulence factors.

S layers, as the most abundant of bacterial cellular proteins, are important model systems for studies of structure, synthesis, assembly, and function of proteinaceous components and evolutionary relationships within the prokaryotic world. S layers also have considerable application potential in biotechnology, biomimetics, biomedicine, and molecular nanotechnology.

I. INTRODUCTION

The different cell wall structures observed in prokaryotic organism, particularly the outermost envelope layers exposed to the environment, reflect evolutionary adaptations of the organisms to a broad spectrum of selection criteria. Crystalline cell surface layers

II. LOCATION AND ULTRASTRUCTURE

Although considerable variation exists in the complexity and structure of bacterial cell walls, it is possible to classify cell envelope profiles into the following

FIGURE 23.1 Schematic illustration of major classes of prokaryotic cell envelopes containing crystalline cell surface layers (S layers). (a) Cell envelope structure of gram-negative archaea with S layers as exclusive cell wall component; (b) the cell envelope as observed in gram-positive archaea and bacteria. In bacteria the rigid wall component is primarily composed of peptidoglycan. In archaea other wall polymers are found; (c) in gram-negative bacteria the S layer is closely associated with the outer membrane. [Modified from Sleytr, U.B., Messner, P., Pum, D., and Sára, M. (eds.) 1996. "Crystalline Bacterial Cell Surface Layer Proteins", R. G. Landes Company/Academic Press, Austin, TX.]

main groups on the basis of structure, biochemistry, and function (Fig. 23.1).

1. Cell envelopes formed exclusively of a crystalline S layer composed of (glyco)protein subunits external to the cytoplasmic membrane (most halophilic, thermophilic and acidophilic, alkaliphilic, barophilic, and gram-negative archaea (Fig. 23.1a).
2. Gram-positive cell envelopes of bacteria with a rigid peptidoglycan containing sacculus of variable thickness outside the cytoplasmic membrane, and gram-positive cell envelopes of archaea with a rigid sacculus composed of pseudomurein or other polymers (Fig. 23.1b).
3. Gram-negative envelopes of bacteria with a thin peptidoglycan sacculus and an outer membrane (Fig. 23.1c).

Although not a universal feature as in archaea, crystalline arrays of (glyco)proteins have been detected as outermost envelope components in organisms of most major phylogenetic branches of gram-positive and -negative bacteria.

Currently, the most useful electron microscopic preparation procedure for detecting S layers on intact cells is freeze-etching (Fig. 23.2). S layer completely covers the cell surface at all stages of cell growth and division in both archaea and bacteria. High-resolution electron microscopical and scanning force microscopical studies revealed, that S-layer lattices can have

FIGURE 23.2 Electron micrographs of freeze-etched preparations of intact bacteria. (a) *Lactobacillus acidophilus* SH1; (b) *Thermoanaerobacterium thermosaccharolyticum* D120-70; (c) *Thermoanaerobacter thermohydrosulfuricus* L111-69. The oblique (a), square (b), and hexagonal (c) S layer completely covers the cell surface. Bars = 100 nm.

FIGURE 23.3 Schematic illustration of the space groups found for S-layer lattices. The unit cells which are the building blocks of the lattice are composed of mono-, di-, tri-, tetra-, or hexamers.

oblique (p1, p2), square (p4), or hexagonal (p3, p6) symmetry (Fig. 23.3) with a center-to-center spacing of the morphological units (composed of one, two, three, four, or six identical monomers) of approximately 5–35 nm. Among archaea, hexagonal lattices were shown to be predominant. S layers are generally 5–25 nm thick and have a smooth outer and a more corrugated inner surface. Since S-layer lattices are monomolecular assemblies of identical subunits they exhibit pores of identical size and morphology (Fig. 23.3). S layers can display more than one type of pores. From high resolution electron microscopical and permeability studies, pore sizes in the range of approximately 2–8 nm and a porosity of the protein meshwork between 30 and 70% have been estimated.

Comparative studies on the distribution and uniformity of S layers have revealed that in some species individual strains can show a remarkable diversity regarding lattice symmetry and lattice dimensions. In some organisms, two or even more superimposed S-layer lattices have been identified.

III. ISOLATION, CHEMICAL CHARACTERIZATION, AND ASSEMBLY

S layers of different bacteria may vary considerably with respect to their resistance to disruption into their monomeric subunits, and a wide range of methods have been applied for their isolation and purification. The subunits of most S layers interact with each other and with the supporting envelope layer through

non-covalent forces. Additionally, secondary cell wall polymers have been recognized as components which facilitate a specific interaction between the S-layer monomers and the cell shape determining peptidoglycan sacculus. Most commonly, in gram-positive bacteria, a complete disintegration of S layers into monomers can be obtained by treatment of intact cells or cell walls with high concentrations of H-bond-breaking agents (e.g. urea or guanidine hydrochloride). S layers from gram-negative bacteria frequently disrupt upon application of metal chelating agents (e.g. EDTA and EGTA), cation substitution (e.g. Na^+ to replace Ca^{2+}), or pH changes (e.g. $\text{pH} < 4.0$). From extraction and disintegration experiments it can be concluded that the bonds holding the S-layer subunits together are stronger than those binding the crystalline array to the supporting envelope layer. There are some indications that S layers of some archaea (e.g. *Thermoproteus* species, and *Methanospirillum hungatei*) are stabilized by covalent bonds between adjacent subunits.

Most S layers are composed of a single, homogeneous protein or glycoprotein species. Sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) revealed apparent molecular masses for subunits in the range of approximately 40–220 kDa.

Comparison of amino acid analyses and genetic studies on S layers from both archaea and bacteria have shown that the crystalline arrays are usually composed of weakly acidic proteins. Typically they contain 40–60% hydrophobic amino acids and possess a low portion, if any, of sulfur-containing amino acids. The isoelectric points pI are in the range of 4–6 but for *Methanothermus fervidus* and for lactobacilli pI values in the range of 8–10 have been determined.

A few post-translational modifications are known to occur in S-layer proteins, including protein phosphorylation and protein glycosylation. In an S-layer (termed A layer) mutant of *Aeromonas hydrophila* the presence of phosphotyrosine residues has been detected by a comparison of the molecular masses obtained from SDS-PAGE and the DNA sequence. A more frequently observed modification of S-layer proteins from archaea as well as bacteria is their glycosylation. Whereas amongst archaea most S layers appear to be glycosylated, evidence for S-layer glycoproteins in bacteria is limited to members of the Bacillaceae. The glycan chains and linkages of these bacterial and archaeal glycoproteins are significantly different from those of eukaryotes (Fig. 23.4). Most archaeal S-layer glycoprotein glycans consist of only short heterosaccharides, usually not built of repeating units. The predominant linkage types are N-glycosidic bonds such as glucose \rightarrow asparagine and

FIGURE 23.4 Schematic presentation of the architectural building plans of S-layer glycoprotein glycans. Type I, extended structure comprising a core region and an S-layer glycan chain (predominantly in bacterial S-layer glycoproteins); Type II, simplified extended structure, comprising a pseudo-core region and an S-layer glycan chain; Type III, heterosaccharide structure. On bacterial S-layer glycoproteins, this type presumably represents only the core structure without repeating units attached. In archaea, however, this type of S-layer glycan is the predominant one. *In vivo*, no repeating units are synthesized by these organisms and the heterosaccharide could consist of 10–20 sugar residues. (Repeating units, composed of two to six monosaccharides, are represented by open symbols; shaded squares indicate residues of core-oligosaccharides; possible variations in length, either in the core or the glycan chain, are indicated by hatched squares; sugar (squares) and amino acid (circles) residues participating in the glycosidic linkage are indicated by full symbols. The star-like symbol at the non-reducing end of the type I glycan represents modification of the terminal unit with O-methyl groups.) [Modified from Schäffer, C. and Messner, P. (2001). *Biochimie* **83**, 591–599.]

N-acetylgalactosamine → asparagine. The opposite situation can be found with bacterial S-layer glycoproteins. To date, only O-glycosidic linkages have been found. Among these are common linkages such as β -galactose → serine/threonine (Fig. 23.5), but also novel linkage types such as β -glucose → tyrosine and β -galactose → tyrosine have been observed. Most of the glycans are assembled of identical repeating units with up to 150 monosaccharide residues. Structurewise they are comparable to lipopolysaccharide (LPS) O-antigens of gram-negative bacteria.

Isolated S-layer subunits of gram-positive and -negative bacteria have also shown the ability to recrystallize on the cell envelope fragments from which they had been removed, on those of other organisms, or on untextured charged or uncharged inanimate surfaces.

To date, the most detailed self-assembly and reattachment experiments have been performed with S

layers from Bacillaceae. S layers of these organisms reveal a high anisotropic charge distribution. The inner surface is negatively charged, whereas the outer face is charge-neutral, approximately pH 7. This characteristic of the S-layer subunits appears to be essential for the proper orientation during local insertion in the course of lattice growth.

Detailed studies have been performed to elucidate the dynamic process of assembly of S layers during cell growth. Freeze etching preparations of rod-shaped cells generally reveal a characteristic orientation of the lattice with respect to the longitudinal axis of the cylindrical part of the cell (see Fig. 23.2). For maintenance of such a good long-range order during cell growth S-layer protomers must have the ability to recrystallize on the supporting envelope layer. Labeling experiments with fluorescent antibodies and colloidal gold/antibody marker methods indicated that different patterns of S-layer growth exist for

from *Campylobacter* and *Caulobacter* strains, all others are produced with a signal peptide, suggesting the classical route of secretion. For the S layers of *Aeromonas salmonicida* and *Caulobacter crescentus* specific secretion pathways, such as an ABC transporter system, have been described.

The remarkable diversity in glycan structures (Fig. 23.4) raised interesting questions about the biosynthesis of prokaryotic glycoproteins. Recently a model has been proposed for how the different N-linked glycans are synthesized in *Halobacterium halobium*. It includes transfer of dolichol-linked saccharides to consensus sequences for N-glycosylation on the S-layer polypeptide. Lipid-activated oligosaccharides with short-chain (C₅₅–C₆₀) dolichol species rather than undecaprenol for S-layer glycosylation were observed not only in *H. halobium* but also in *Haloferax volcanii* and *M. ferrovidus*. In comparison to archaeal S-layer glycoproteins, less detailed information is available regarding the biosynthesis of glycosylated S layers of bacteria. Only recently, the exact positions of glycosylation sites have been determined on the sequenced structural gene *sgsE* of *Geobacillus stearothermophilus* NRS 2004/3a (Fig. 23.5). The nucleotide sequences of three S-layer glycan biosynthesis clusters are now completed which show the molecular organization of the glycosylation machinery of S-layer glycan biosynthesis in bacteria. Functional expression of several nucleotide-activated sugars, which are constituents of the mature S-layer glycans, has been achieved. Currently, we are investigating the remaining genes in the clusters which code for enzyme proteins such as glycosyl transferases, transporters of the glycan chains across the cytoplasmic membrane, modification enzymes, and ligases which eventually link the S-layer glycan to the S-layer polypeptide.

V. FUNCTIONAL ASPECTS AND APPLICATION POTENTIAL

Since prokaryotic organisms possessing S layers are ubiquitous in the biosphere, it can be expected that the porous network of monomolecularly arranged (glyco)proteins has evolved as the result of quite diverse interactions of the bacteria with specific environmental and ecological conditions.

Although relatively few data are available on specific functions of S layers, there is strong evidence that the crystalline arrays have the potential to function as: (i) cell shape-determining framework; (ii) protective coats, molecular sieves, and molecule or ion traps; and (iii) promoters of cell adhesion and surface recognition (Table 23.1).

TABLE 23.1 Functions of S layers

Determination of cell shape and cell division (in archaea that possess S layers as the exclusive wall component)
Protective coats
Prevents predation by <i>Bdellovibrio bacteriovorus</i> (in gram-negative bacteria)
Phage resistance by S-layer variation
Prevention or promotion of phagocytosis
Adhesion site for exoenzymes
Surface recognition and cell adhesion to substrates
S layers function as physicochemical and morphological well-defined matrices
Masking the net negative charge of the peptidoglycan-containing layer in Bacillaceae
Isoporous molecular sieves
Molecular sieves in the ultrafiltration range
Delineating in gram-positive bacteria a compartment (periplasm)
Preventing non-specific adsorption of macromolecules
Virulence factor in pathogenic organisms
Important role in invasion and survival within the host
Specific binding of host molecules
Protective coat against complement killing
Ability to associate with macrophages and to resist the effect of proteases
Production of S layers which do not immunologically cross-react (S-layer variation)
Fine grain mineralization

Sleytr, U. B. (1997). *FEMS Microbiol. Rev.* 20, 5–12.

A. Cell shape determination

Because of their structural simplicity and from a morphogenetic point of view, it was suggested that S layers, like lipid membranes, could have fulfilled barrier and supporting functions as required for self-reproducing systems (progenotes) during the early period of biological evolution.

Analysis of the distribution of lattice faults of hexagonal S layers of archaea which possess an S layer as their sole cell wall constituent (Fig. 23.1a) provided strong evidence that complementary pairs of pentagons and heptagons play an important role in site for the incorporation of new subunits, in the formation and maintenance of the lobed cell structures, and in the cell fission process. The latter appears to be determined by the ratio between the increase in protoplast volume and the increase in actual S-layer surface area during cell growth.

B. S layers related to pathogenicity

Particular attention has been paid to S layers present on pathogenic organisms. Crystalline arrays present on members of the genera *Aeromonas* and *Campylobacter* comprise one of the best studied S-layer systems. In *Aeromonas salmonicida*, which causes furunculosis in salmon, generally an S layer is

required for virulence. The S layer physically protects the infecting cells against proteolysis and complement and is essential for macrophage infiltration and resistance. In *Campylobacter fetus* subspecies *fetus*, the agent that causes abortion in sheep and cattle and various systemic infections or acute diarrheal illness in humans, S layers appear to make the cells resistant to phagocytosis and to bactericidal activity of serum.

Crystalline surface layers identified on other pathogens of humans and animals, including species of *Bacteroides*, *Brucella*, *Chlamydia*, *Cardiobacterium*, *Rickettsia*, *Wolinella*, *Treponema*, *Clostridium*, and *Bacillus*, may be of similar functional relevance as virulence factors.

C. S layers as molecular sieves and promoters for cell adhesion and surface recognition

Data obtained by high-resolution electron microscopy indicate that S layers are highly porous structures with pores of defined size and morphology (see Fig. 23.3). Permeability studies on S layers of mesophilic and thermophilic Bacillaceae provided information on their molecular sieving properties. For example, S layers of *G. stearothermophilus* revealed sharp exclusion limits for molecules larger than 30–40 kDa, indicating a limiting pore diameter in the crystalline protein meshwork of about 4.0 nm. With some mesophilic Bacillaceae, pore sizes as small as approximately 2.5 nm have been determined. These permeability studies also showed that the pores in the S-layer membranes have a low tendency for fouling, a feature regarded as essential for an unhindered exchange of nutrients and metabolites up to a defined molecular size.

S layers acting as molecular sieves have the potential to function not only as barriers preventing molecules from entering the cell (e.g. lytic enzymes, complements, antibodies, and biocides). They can also generate a functional equivalent to the periplasmic space of gram-negative bacterial envelopes in preventing the release of molecules (e.g. enzymes and toxins) from the cell. On the other hand, S layers of Bacillaceae were found to function as adhesion site for cell-associated exoenzymes.

Cells of *Aquaspirillum serpens* and other gram-negative species were shown to be resistant to predation by *Bdellovibrio bacteriovorus* when they were covered by an S layer. However, S layers of different organisms (e.g. Bacillaceae) were demonstrated to act as specific sites for phage adsorption. Analysis of phage-resistant mutants of *Bacillus sphaericus* showed that although the crystalline arrays were present on

all mutants, the molecular weight of the S-layer subunits had changed.

With regard to cell adhesion and cell recognition properties of S layers, an important aspect is the frequently observed anisotropic distribution of charged groups on both faces of the (glyco)protein lattice. Most Bacillaceae possessing S layers reveal a charge-neutral outer surface, which physically masks the net negatively charged peptidoglycan sacculus. In comparison with S-layer-deficient strains, S-layer-carrying Bacillaceae have also shown a greater ability to adsorb to positively charged or hydrophobic surfaces.

D. Application potential

Based on the data obtained in fundamental studies on S layers, a considerable potential in biotechnological and nonbiological applications is evident. Applications for S layers have been found in the production of isoporous ultrafiltration membranes, as supports for a defined covalent attachment of functional molecules (e.g. enzymes, antibodies, antigens, protein A, biotin, and avidin) as required for affinity and enzyme membranes, in the development of biosensors, or in solid-phase immunoassays. S-layer membranes have also been used as support for Langmuir lipid films or liposomes, mimicking the molecular architecture of gram-negative archaea and virus envelopes (see Fig. 23.1a). S-layer fragments or self-assembly products are well suited for a geometrically well-defined covalent attachment of haptens and immunogenic or immunostimulating substances. These haptened S-layer structures act as strong immunopotentiators. Finally, cloning and characterization of genes encoding S-layer proteins, opened new areas of applied S-layer research. Incorporation of functional domains without hindering self-assembly of S-layer subunits into regular arrays will lead to new types of recombinant vaccines, affinity matrices, diagnostics, biocompatible surfaces, and in combination with liposomes as drug-targeting and -delivery systems as well as systems for gene therapy. Recently it was demonstrated that S layers can be employed in non-life science nanostructure technologies (e.g. non-linear optics and molecular electronics) and as matrix for controlled biomineralization.

GLOSSARY

alkanotrophic Capable of assimilating propane, *n*-butane, and other *n*-alkane gases and liquid hydrocarbons as sole carbon and energy sources.

hyphomycetes Grouping of asexually reproducing fungi ("fungi imperfecti") in which the asexual spores (conidia) are produced on loose, cottony hyphae.

lyophilization The process of simultaneously freezing and drying materials under a vacuum.

patent depository In accordance with patent laws of most countries, novel microorganisms involved in a patent must be deposited in a recognized patent depository. Signatories to an International Budapest Treaty agreed that deposits in any approved International Depository Authority will be acceptable for meeting their patent office deposition requirements. (See, e.g., <http://www.atcc.org/ProgramsAndServices/PatentDep.cfm>)

A **Stock Culture Collection** is a repository for strains or varieties or species of organisms developed for the purpose of preservation and distribution of a useful range of the organisms. A distinction can be made between genetic stock collections, which are primarily mutant derivatives of one or more founder strains, along with related non-mutant strains, and germplasm and type culture collections, which have more heterogeneous holdings. This article is limited to microbial stock centers, although a few nonmicrobial centers are cited in recounting the history of genetic stock collections. The descriptions of early stock

centers are presented in approximately chronological order, followed by genetic stock centers and by the later, national collections and consortia, which are grouped by country. These and more specialized collections are also listed under type of organism. Descriptions and access information are presented in a Table of Stock Centers.

I. FEDERATIONS SPONSORING DATABASES THAT IDENTIFY COLLECTION RESOURCES

The World Federation for Culture Collections (WFCC) is a Commission of the International Union of Biological Sciences (IUBS) and a federation within the International Union of Microbiological Societies (IUMS) (<http://wddcm.nig.ac.jp/wfcc/AboutWFCC.html> and www.wfcc.info). Its purpose is to support and promote establishment of culture collections. In collaboration with the Microbial Resources Centres (MIRCEN) and other organizations described below, it sponsors a database that is a directory of culture collections, the World Data Centre for Microorganisms, WDCM. This database began as a registry of worldwide culture collections initiated by V. B. D. Skerman at the University of Queensland in the 1960s. The registry was published in 1972 as the World Directory of Collections of Cultures of Microorganisms (WDCCM) by the WDCM, as a result of a proposal by the Japanese Federation of Culture Collections. The Directory was supported by the United Nations Educational, Scientific, and Cultural Organization

(UNESCO), the World Health Organization (WHO), the Australian Commonwealth Scientific and Industrial Research Organization (CSIRO), and the Canadian Research Council and its second edition in 1982 also by the United Nations Environmental Program (UNEP). Its fourth edition was published in 1993. Currently, the WDCM provides an on-line database of the collections and also of databases on microbes and cell lines. The server is located at the National Institute of Genetics in Japan (<http://wdcm.nig.ac.jp>; and <http://wdcm.nig.ac.jp/DOC/menu3.xml>). It includes large and small collections, numbering nearly 500, located in public and private institutions in 55 countries. Particularly useful is an index of species and serovars held by culture collections with links to the culture collections holding the selected strain of interest. Many of these collections are cited in later sections of this article. The species list is found at http://wdcm.nig.ac.jp/wfcc/species_list.html and the index at <http://wdcm.nig.ac.jp/index.html>. The WDCM also allows querying by species or collection (e.g. <http://wdcm.nig.ac.jp/fsearch.html>) or by key word (<http://wdcm.nig.ac.jp/DOC/menu2.xml>) and presents a list of consulting services provided by the various stock centers (http://wdcm.nig.ac.jp/wfcc/services_list.html) and a listing by country (<http://wdcm.nig.ac.jp/hpcc.html>).

MIRCEN is a UNESCO-sponsored network of academic and research institutes to foster collaboration in environmental, applied microbiological, and biotechnological research in cooperation with the National Commissions of Member States of the United Nations (<http://www.asm.org/International/index.asp?bid=14221>). MIRCEN is also a sponsor of the WDCM database. This is acknowledged by the official designation of the database as the WFCC-MIRCEN WDCM. *Rhizobium* is a particular focus for MIRCEN, and other areas include biotechnology, aquaculture, and bioinformatics. Historically UNESCO's role in preserving microbial diversity dates to 1946 (see DaSilva, 1977). Currently, the largest members of the culture collection network include the Belgian Coordinated Collections (BCCM), the German Collection (DSMZ), Braunschweig, The Culture Collection of Hungary, the National Collection of Type Cultures (NCTC) in London, C.A.B. International Mycological Institute (IMI), and the American Type Culture Collection (ATCC), all of which are described in sections that follow. However, the network also supports collecting and coordination of collections at MIRCEN centers and groups throughout the world, including Bangkok, Dakar, Hawaii, Nairobi, and sites in African, Latin American, European, Arab, and Asian countries too numerous to mention. MIRCEN also sponsors a server located in Cairo for searching microbial collections. In addition to the

WDCM, the bioinformatics area of MIRCEN includes BITES, the Biotechnological Information Exchange System in Slovenia, and Bioinformatics MIRCEN at the Karolinska Institute in Stockholm (<http://home.swipnet.se/~w-2586/jacky/mircen>).

Other organizational sponsors of the WDCM are the National Institute of Genetics Center for Information Biology of Japan (CIB), the Japan Science and Technology Corporation (JST), the Committee on Data for Science and Technology (CODATA), UNESCO, and UNEP.

The Microbial Strain Data Network (MSDN) is a nonprofit organization that provides links to databases of interest to microbiologists and biotechnologists. It is sponsored by UNEP. The secretariat is in Sheffield, UK, and it is managed by an international committee. The European node was established in conjunction with CABRI, the Common Access to Biotechnological Resources and Information project. The Institute of Microbiology of China is a collaborator and has established an MSDN node in China as part of the Microbial Information Network of China, and there are nodes in India and Brazil as well. Databases for small, specialized collections as well as the large heterogeneous national and international collections are included in the MSDN Web site. It allows searches of databases in the Czech Republic, Siberia, India, Japan, Russia, Slovenia, Argentina, Bulgaria, and the UK (<http://www.im.ac.cn/msdn.html>, <http://www.bdt.fat.org.br/mrcs>, <http://wdcm.nig.ac.jp/msdn/MSDN.html>, and <http://panizzi.shef.ac.uk/msdn>).

The CABRI consortium provides the MSDN node in the UK and for Europe, providing links to MSDN, several of the large European culture collections, and cell culture and biological materials sources (<http://www.cabri.org/collections.html>).

The National Veterinary School of Toulouse has a website by J.P.M. Euziby with an extensive list of culture collections throughout the world (www.bacterio.cict.fr/collections.html) including links to websites (www.bacterio.cict.fr/links.html).

The Microbial Germplasm Database (MGD) at Oregon State University emphasizes strain collections available from individual university, industry, government, and National Science Foundation (NSF)-supported laboratories and research stations, in contrast to public collections. It includes algae, bacteria, fungi, and viruses, and provides contact information for the laboratory collections. It also publishes an on-line newsletter. The MGD is supported by the US Department of Agriculture (USDA) and NSF (<http://mgd.nacse.org/cgi-bin/mgd>). Bergey's Manual Trust (responsible for publishing new editions of the classic authority on bacterial taxonomy, *Bergey's*

Manual of Determinative Bacteriology) maintains on its Web site a list of major collections and consortia (<http://www.cme.msu.edu/bergeys/resourceinfo.html>).

There are also directories with more general purposes which include information about stock collections, for example, <http://www.seaweed.ie>, <http://biodiversity.uno.edu/~fungi/collect.html>, and MycDB. MycDB is sponsored by the WHO and Follereau Foundation, originally at the Royal Institute of Technology in Stockholm and now at the Pasteur Institute in Paris, and is primarily a source of molecular biology information on mycobacteria, but it does provide information on availability of stocks of mycobacterial species in stock centers (<http://www.pasteur.fr/mycdb>). Databases that link or search multiple collections are also presented at the end of Table 24.1 (Section VII).

II. EARLY GERMPLASM AND TYPE CULTURE COLLECTIONS

The Collection of the Bacterial Strains of Institut Pasteur (CIP) traces its origins to Dr. Binot, who began to collect strains in 1891. It is a private, non-profit collection that has become enlarged primarily by collaboration with the research laboratories of the Pasteur Institute. It maintains, preserves (by lyophilization since 1952), distributes, and provides information about strains. The CIP joined the World Federation of Culture Collections (WFCC) and the European Culture Collections Organization (ECCO, a collaborative organization for curators founded in 1982), and it is part of the Microbial Information Network Europe (MINE). Querying for strains can be performed at <http://www.pasteur.fr/CIP>. The individual records include links to other collections, as well as descriptions and literature references.

The Mycological Collection of the Catholic University of Louvain [now part of the Belgian Coordinated Collections of Microorganisms (BCCM)—see National Collections and Consortia in Table 24.1] was founded in 1892–1894 by Prof. Philibert Biourge, and in 1901 Biourge's *Penicillium* collection was augmented with Prof. F. Dierckx's *Penicillium* and *Aspergillus* strains. During World War I, however, much of the collection disappeared, with accessions increasing again after the war. It was managed in the 1930s through the 1960s by Prof. P. Simonart, then by Prof. G. L. Hennebert as it merged with his fungus collection, which had begun in 1956. Other significant mergers brought in hyphomycetes from Prof. J. A. Meyer and the yeast collection of Biourge. The current holdings are described in Table 24.1 as part of the BCCM consortium (<http://www.belspo.be/bccm>).

The Uppsala University Culture Collection (Mykoteket or UPSC) has its origins intermingled with that of the Botanical Museum at Uppsala University and its extensive herbarium of plants, algae, and fungi, which date back to 1785 and C. Thunberg, a disciple of Linnaeus, and more specifically to the E. Fries fungal herbarium of the mid-1800s. The current fungal culture collection, the UPSC or Mycoteket, holds over 3000 strains. Its on-line database is found at <http://www-hotel.uu.se/evolmuseum/mykotek/index.html>.

The American Museum of Natural History/Society of American Bacteriologists Collection originated with an 1899 recommendation by the Society of American Bacteriologists (now the American Society for Microbiology) calling for a central repository for bacterial cultures. Such a collection was begun at the American Museum of Natural History in New York by MIT professor C.-E. A. Winslow in 1911.

Similarly, a proposal by the Association Internationale des Botanistes led to the establishment of the Centraal Bureau voor Schimmelcultures (CBS) of the Netherlands in 1903 as a central collection of fungi, with 80 cultures available in 1906. In 1922 it moved to Delft Technical University. It was initially supported privately, but it became an institute of the Royal Netherlands Academy of Arts and Sciences, financially supported by the Dutch government, in 1968. The CBS includes as a separate unit the Phabagen Collection (see Microbial Genetic Stock Centers) and the Bacterial Collection of Kluyver Laboratory of Microbiology (LMD), which have merged to become the Netherlands Culture Collection of Bacteria (NCCB). See the section on national collections in Table 24.1. A goal of the CBS is to preserve representatives of virtually all fungal groups that can be cultured, and the cultures currently number 35,000 with annual increases of approximately 1000 (<http://www.cbs.knaw.nl/www/collection.htm> and <http://www.cbs.knaw.nl/www/cbshome.html>).

The USDA Culture Collection also had its origins in the early 1900s. Although plant germplasm is the best-known of the collections supported and administered by the US Department of Agriculture, the early history of US microbial germplasm and genetic stock collections finds the USDA in a central role. Drs. Charles Thom and Margaret Church established a USDA collection in Washington, DC, in 1913 that had begun with Dr. Thom's mold cultures in Connecticut and developed into the source of strains for both the USDA/Agricultural Research Service (ARS) Culture Collection and the American Type Culture Collection.

The USDA/ARS Culture Collection developed from this early USDA collection. In 1940, the Northern Regional Research Laboratory (NRRL) opened in

Peoria, and Dr. Kenneth Raper formally established the ARS Collection there. (The laboratory is now named the National Center for Agricultural Utilization Research, NCAUR.) The NRRL collection included approximately 2000 Thom and Church cultures of molds, deposits of citric acid-producing aspergilli, bacterial strains, and L. J. Wickerham's yeasts. Large-scale use of lyophilization (freeze-drying) for preserving cultures was pioneered at the NCAUR for these cultures. Collections contributed to the ARS collection from later research programs include Mucorales, Taphrina, filamentous fungi, yeasts, aerobic spore-forming bacteria, rhizobia, and actinomycetes. The collection accepts strains that are nonpathogenic to humans and animals and are not fastidious in their growth requirements. Plant and animal cell lines are not accepted. Active research programs of curators and other scientists at the center, as well as outside researchers, utilize and enhance the collections and their applications. A notable, historic contribution was the development of an industrial process for producing penicillin during World War II. The collections include a patent culture collection as well as the "open" public collection, totaling over 80,000 strains (http://nrml.ncaur.usda.gov/the_collection3.htm and <http://nrml.ncaur.usda.gov>). On-line databases for the Actinomycetales, bacterial, and filamentous fungal collections can be searched at <http://nrml.ncaur.usda.gov/searchcc.htm>.

The USDA/ARS also maintains a Collection of Entomopathogenic Fungal Cultures (ARSEF), begun in the 1970s at the University of Maine and moved to the Plant Protection Research Unit on the Cornell campus in Ithaca, New York. A fungal herbarium is also associated with this collection (<http://www.ars.usda.gov/is/np/systematics/fungibact.htm>).

A third USDA/ARS collection is the National *Rhizobium* Germplasm Resource Center. The first cultures were isolated from northern Virginia in 1913 and increased by USDA scientists in response to research demands, particularly in the 1930s and 1940s. Because of its international agricultural significance, it was initially funded by the US Agency for International Development, and in the 1980s it was designated a UNESCO Microbiological Resource Center (see MIRCEN above). Since 1990, the Agricultural Research Service has supported the collection (<http://bldg6.arsusda.gov/pberkum/Public/cc1a.html>). A searchable index can be found at the Web site for the Germplasm Resources Information Network of the USDA/ARS (<http://www.ars-grin.gov/cgi-bin/nmgp/rhy/search.pl>).

An algal collection developed by Prof. E. G. Pringsheim and colleagues at the University of Prague (Charles University) formed the basis for both

the CCAP, the Culture Collection of Algae and Protozoa, now in the UK, and the CCALA, the Culture Collection of Autotrophic Organisms in the Czech Republic. The collection developed by Pringsheim, V. Czurda, and F. Mainx moved with Prof. Pringsheim to England and was later expanded and directed by Prof. E. A. George at Cambridge University, with support from the UK Natural Environment Research Council. Its two current components, the Institute of Freshwater Ecology (IFE) collection and Dunstaffnage Marine Laboratory collection, are cited in the algal collections section (see Table 24.1). The algal collection of Profs. V. Uhlir and Pringsheim in Prague was merged with the algal collection at the Institute of Microbiology, Czech Academy of Sciences at Trebon, to form the CCALA, also cited with algal collections in Table 24.1.

The American Type Culture Collection (ATCC) was founded in 1925 by representatives from the National Research Council, the Society of American Bacteriologists, the American Phytopathological Society, the American Zoological Society, and the McCormick Institute for Infectious Diseases. It was located at first at the McCormick Institute in Chicago, moving in 1937 to the Georgetown University School of Medicine and to houses in Washington, DC, in 1947 and 1956. It was incorporated as an independent, non-profit institution in 1947. It then included microorganisms, animal and plant viruses, and cell lines. In 1964, it moved into a facility in Rockville, Maryland, and in 1998 to Manassas, Virginia. It has been supported by many grants from the US National Science Foundation (NSF) and National Institutes of Health (NIH) directed toward the various specialized collections and activities—hybridomas, bacterial collections, databases, yeasts, protozoa, probes, clones, etc.—as well as by users' fees. The holdings are extensive, with over 14,000 bacterial strains, 500 viral strains, and 26,000 strains of 6500 yeast and fungal species. It is also an official US patent repository and conducts workshops and education sessions. It is the distribution source for microbial genome clones for completely sequenced prokaryotic genomes from the Institute for Genomic Research (TIGR) in Maryland and for many cDNA clones (<http://www.atcc.org>).

The International Mycological Institute (IMI) Culture Collections are part of the institute founded in 1920 and is currently part of CAB (originally called Commonwealth Agricultural Bureaux) International, a nonprofit organization supported by 32 governments. The current collection has over 16,500 strains of filamentous fungi, yeasts, and bacteria. It is a patent depository and offers identification, preservation, testing, consultation, and training services and

undertakes applied research. A database may be searched at <http://www.cabi-bioscience.org/html/ResourceCentre.htm>. (See also [/ReferenceCollections.htm](#))

III. EARLY GENETIC STOCK CENTERS

In most cases, genetic stock centers originated when early geneticists working with the species recognized that the stocks were valuable for future research and made accommodations for preserving and disseminating these stocks. The realization of the need for the stocks was often accompanied by the realization that a means for disseminating new scientific results in a rapid and somewhat informal way was also required for advancing scientific progress with the organism. For most stock centers the information function has progressed from species-specific newsletters and strain lists to comprehensive on-line databases.

Among the earliest stock centers in the United States are the *Drosophila* Stock Center and the Maize Cooperation Genetics Stock center. The *Drosophila* center grew from the mutant collection originating with T. H. Morgan and his students at Columbia, beginning in 1913. Their stocks, maintained by Bridges, were provided to anyone requesting them. In 1928, when Morgan, Bridges, Sturtevant, and the collection moved to the California Institute of Technology, that became the site of the *Drosophila* stock center and of the stock list published in the *Drosophila* Information Service. This stock center is currently at the University of Indiana and includes approximately 6000 stocks (T. Kaufman and K. A. Matthews, <http://flybase.bio.indiana.edu/stocks>).

The Maize Genetics Cooperation Stock center had its origins in the 1928 Winter Science meetings in New York, when a group of maize geneticists discussed work on the maize linkage maps and the idea of an organized Maize Genetics Cooperation. A formalized proposal in 1932 included provision for the Maize Genetics Cooperation News Letter and the Maize Genetics Cooperation Stock Center. Marcus M. Rhoades served as first secretary of the Newsletter and first director of the stock center. Currently, the Maize Cooperation Stock Center is at the University of Illinois, USDA/ARS (M. Sachs), and the Maize Genetics Cooperation Newsletter is produced at ARS/USDA, University of Missouri (E. Coe). The collection includes nearly 80,000 pedigreed samples, including alleles of several hundred genes, combinations of such alleles, chromosome aberrations, ploidy variants, and other variations. Details about the collection, its history, available stocks, and request forms can be found at

<http://w3.ag.uiuc.edu/maize-coop/mgc-info.html>. (The newsletter can be found on the Maize Genome Database site at <http://www.agron.missouri.edu/mnl.html>.)

IV. MICROBIAL GENETIC STOCK CENTERS

A. Bacterial Genetic Stock Centers

Sexuality and the ability to make genetic crosses between bacteria was discovered in *E. coli* in the 1940s. The use of microorganisms to explore the relationship between genes and biochemical pathways also became established in that decade. Individual laboratories accumulated large numbers of *E. coli* mutants, primarily derivatives of the wild-type isolate *E. coli* K-12. In the 1960s, it became apparent that a national repository would greatly aid the free exchange of strains and the advance of molecular genetics.

At that time, support from the US NSF was a critical element in developing such a resource, and the NSF supported a proposal to begin with E. A. Adelberg's Yale University collection of stocks and add important strains and sets of strains from laboratories worldwide. This became the *E. coli* Genetic Stock Center (CGSC) at Yale, curated for 25 years (until 1993) by B. Bachmann. The CGSC holds over 8000 strains and a plasmid library of cloned segments covering nearly all of the *E. coli* genome. Unlike the previous two centers, a newsletter was not associated with the founding of the stock center, but it soon assumed the functions of registering gene names and allele numbers, as set forth in the widely accepted guidelines for bacterial nomenclature by Demerec *et al.* (1966), and meeting subsequent needs for registry to avoid duplication of designations for deletions, insertions, and F-primes. It also took on responsibility for periodic publishing of the linkage map for *E. coli* K-12, and with that came a contingent role of "authenticating" canonical gene symbols. These information roles provided a natural progression to an on-line database covering gene names, functions, map locations, strain genotypes, mutation information, and supporting documentation, as well as links to information from other bacterial, genetic, and molecular biology databases. The development and maintenance of the database, as well as the Stock Center itself, have been supported by the NSF (<http://cgsc.biology.yale.edu>).

Phabagen, the Phage and Bacterial Genetics Collection, includes 5000 mutant bacterial strains (*E. coli* and *Agrobacterium tumefaciens*), 450 cloning vectors, 800 other plasmids, two plasmid-containing

gene banks of *E. coli*, and over 100 phages. It was established in the early 1960s with deposits of bacterial mutants from researchers of the Working Community Phabagen. It has, since 1990, been part of CBS (see national consortia in Table 24.1) and is merging with the Kluyver Institute's LMD Collection to form the NCCB, the Netherlands Culture Collections of Bacteria (<http://www.cbs.knaw.nl/nccb/database.htm>).

The National Institute of Genetics of Japan (NIG) established a Genetic Stock Center in 1976 and developed an extensive collection of *E. coli* strains. In 1997 it was reorganized as the Genetic Strains Research Center, Microbial Genetics Center, and the Center for Genetic Resource Information. The microbial collections include approximately 4000 strains of *E. coli* genetic derivatives and 400 cloning vectors (<http://shigen.lab.nig.ac.jp/ecoli/strain> and <http://shigen.lab.nig.ac.jp/cvector/cvector.html>).

The *Salmonella* Genetic Stock Center (SGSC) at the University of Calgary, British Columbia, Canada, had its origins in the laboratory of M. Demerec at Cold Spring Harbor Laboratory and Brookhaven National Laboratory, Long Island, New York, in the 1950s and 1960s as genetic derivatives primarily of *Salmonella typhimurium* (or *Salmonella enterica*, subsp. *enterica*, serovar Typhimurium) strain LT2. It remained with the Demerec laboratory during his long career, and then it was moved and expanded at the University of Calgary by K. E. Sanderson. It currently has several thousand strains, cosmid and phage libraries, and a set of cloned genes. Many of the mutant strains are organized into special purpose kits, useful for specific genetic techniques or analyses. In addition to the mutants, it has the *Salmonella* Reference Collection (SARC) representing all subgenera of *Salmonella*. The SGSC is supported by the Natural Sciences and Engineering Research Council of Canada (<http://www.acs.ucalgary.ca/~kesander>).

Bacillus subtilis has been studied as the model spore-forming bacterium, and many mutant strains have been isolated. In 1980 the *Bacillus* Genetic Stock Center was founded at Ohio State University. It includes over 1000 genetically characterized *B. subtilis* strains, over 200 strains of other *Bacillus* species, and *E. coli* strains bearing shuttle plasmids or cloned *Bacillus* DNA. It publishes a newsletter and a genetic map for *Bacillus subtilis*. The NSF supports this stock center (<http://bacillus.biosci.ohio-state.edu>).

B. Fungal and Algal Genetic Stock Centers

The Fungal Genetic Stock Center (FGSC) was organized as a result of recommendations by the Genetics

Society of America in 1960. It was originally located at Dartmouth College, directed by R. Barratt, then moved to California State University in Humboldt, and in 1985 to the University of Kansas Medical Center. Its holdings include nearly 9000 strains of filamentous fungi, mostly genetic derivatives of *Neurospora crassa*, *Aspergillus nidulans*, and *Aspergillus niger*, but include also *Neurospora tetrasperma* and isolates of other *Neurospora* and *Aspergillus* species. The collection also contains *Fusarium* species and mutants, and *Nectria* and *Sordaria* mutants and species. The stock center publishes, mails, and makes available on its website the Fungal Genetics Newsletter, meeting abstracts and announcements, and a bibliography. The website has information on genes, alleles, and maps, and the center supplies plasmids, clones, and gene libraries for *N. crassa* and *A. nidulans*, as well as the strains. The FGSC is supported by the NSF (<http://www.fgsc.net>).

The Yeast Genetic Stock Center (YGSC) originated at the University of California at Berkeley in 1960, founded and directed by R. Mortimer for genetic derivatives of *Saccharomyces cerevisiae*, primarily originating from "founder" stocks of C. Lindgren at Southern Illinois University in Carbondale. The Mortimer laboratory also published linkage maps and linkage data summaries. Maps and linkage data, but not stock descriptions, are currently provided by the *Saccharomyces* Genome Database (<http://www.yeastgenome.org>). The 1200 genetic stocks in the collection were moved in 1998 to the ATCC, and stock information is available from there (<http://www.atcc.org/SpecialCollections/YGRRRC.cfm>).

The Peterhof Genetic Collection of Yeasts (PGC) is located in the Biotechnology Center at St. Petersburg State University in Russia. It has over 1000 genetically marked yeast strains, mainly lines originating from a diploid cell of an inbred strain of *Saccharomyces cerevisiae* (the Peterhof genetic lines, as distinguished from the Carbondale origin of the strains in the YGSC), other genetically marked *S. cerevisiae* strains, and segregants of crosses between the latter and the Peterhof lines. The collection is searchable via the MSDN, at <http://panizzi.shef.ac.uk/msdn/>.

The *Chlamydomonas* Genetics Center (CGC), at Duke University, collects, describes, and distributes nuclear and cytoplasmic mutant strains, and genomic and cDNA clones, of *Chlamydomonas reinhardtii*, which has served as a model organism for algae and for photosynthetic organisms. It is supported by the NSF. The Web and gopher sites provide, in addition, information on genetic and molecular maps of *Chlamydomonas reinhardtii*, plasmids, sequences, and bibliographic citations (<http://www.biology.duke.edu/chlamy>).

C. Information management at Genetic Stock Centers

The dissemination of information was often an equal partner with the dissemination of stocks in the call by the scientific community for founding of the stock centers. Some stock centers distributed printed catalogs, and others published periodic announcements summarizing their holdings. Many stock center curators or directors took responsibility for publishing frequently updated versions of the genetic map for the major organism in their collection. In 1988, a workshop on computerization of databases for genetic stock collections was held in conjunction with the 16th International Congress of Genetics, August 1988, Toronto. This meeting acknowledged the information functions of the stock centers in describing and distributing the organisms and also in producing genetic maps, standardizing allele designations, and documenting gene function and nomenclature, and it discussed and made recommendations for facilitating database development and database construction. In the US, the NSF and other funding agencies played a prominent role in encouraging stock centers to recognize the need for modernization and computerization of their valuable records.

Development of the Internet and the World Wide Web has altered and enhanced the performance of these information functions and the way that users interact with the stock centers. It has allowed information formatted in many different ways at the many stock collections sites to be searched and presented to the user and allows links among stock centers and between stock centers and databases with sequence and other types of information. It allows the centers to provide on-line direct access to the information about stocks, gene characterization, and the genetic map updates. Citations of Web addresses for all microbial stock centers and ancillary information associated with them have been given throughout this article and are included as part of the entries in Table 24.1.

V. NATIONAL COLLECTIONS AND CONSORTIA WITH BROAD HOLDINGS

During the past three decades, many countries have moved to consolidate the administration of their stock centers into a single administrative and information unit or federation. Examples of some of these consortia are presented in Table 24.1 by country. Particularly extensive consortia include those in the United Kingdom, France, Belgium, and the Netherlands, as

well as the USDA collections. These and other national collection consortia in the Czech Republic, Poland, Russia, the Ukraine, China, Japan, Indonesia, Canada, and Brazil are described under the heading National consortium, comprehensive in Table 24.1. Other countries have long had centralized national collections rather than individual specialized or general collections. Such collections are listed under National, comprehensive type collections in Table 24.1. The DSMZ in Germany is one of the largest, and others are located in Belarus, Bulgaria, Hungary, India, Thailand, Taiwan, New Zealand, and Mexico. Still other comprehensive collections serve national and international communities but are not administered or entirely supported by governmental agencies. For example, the ATCC (American Type Culture Collection) in the United States is only partially supported by federal grants and is administered as an independent, nonprofit institution. Such collections are type classified as Other—comprehensive in Table 24.1. The US collections are not organized under any single coordinating administrative body, although the USDA/ARS collections are coordinated through the USDA and the ATCC represents a consolidation of many different types of collections. There is a US Federation of Culture Collections to promote cooperation and information sharing among the diverse stock centers. It cooperates with the International World Federation of Culture Collections in sponsoring international meetings among directors and curators of stock collections. The International Mycological Institute is internationally supported (CAB International), with a secretariat in the UK, and this collection and university collections in Sweden, Finland, and Australia, and Japan's Institute for Fermentation (IFO) Collection in Osaka are classified as Other—comprehensive in Table 24.1. National collections that are specialized rather than comprehensive are presented under organism-specific headings in Table 24.1.

VI. ORGANISM-SPECIFIC COLLECTIONS

The organism-specific collections are presented in Table 24.1 under the following broad headings: bacteria; fungi, including yeasts; and algae, protozoa, and cyanobacteria. Type headings provide a more specific indication of the holdings. Previously described collections, in either the national consortia part of the table or in narrative sections, are cited again in Table 24.1 in order to expedite locating the collection and its Web URL.

VII. A TABLE OF STOCK COLLECTIONS

To facilitate look-up of specific kinds of collections and especially to facilitate locating the Web address of a collection, a tabular rather than text format is used to present collections by type and country, to provide

brief descriptions of the collections, and to cite the Web addresses. Clearly a totally comprehensive listing of such diverse and widespread resources is not possible, and regrettable oversights have no doubt occurred. Widely used and Web-accessible sites have been emphasized. See legend for information on searching for collections not listed in the table.

TABLE 24.1 Representative stock collections: location, description, and access

Many of the descriptions briefly cite special functions, history, and holdings, if this information has not been previously cited. Preservation and distribution functions are assumed in all cases and are not cited specifically. The table first presents comprehensive collections, with country presented in uppercase, then organism-specific collections (Bacteria; Fungi, Algae, protozoa, and cyanobacteria), and finally databases that cover multiple collections. Web URLs may change at any time, and searches may be necessary to update those shown in the table. No claim can be made that this is an exhaustive compilation of all the world's stock centers. Comprehensive database searches and links given at the end of the table can be used to search for collections not listed in the table. For example, <http://wdcm.nig.ac.jp/CCINFOSearch.html> will retrieve all WDCM collections by country or organism. (See last entry in the Table.)

Type	Country	Designation	Description	Web URL
Comprehensive				
National consortium, comprehensive	United Kingdom	UK National Collections include the following: NCTC, National Collection of Type Cultures, London	See individual collection descriptions below Has about 5000 cataloged strains of medical and veterinary significance and 13,000 uncataloged strains. A patent and safe depository. Jointly with the DSM (Germany) is the Resource Centre for plasmid-bearing bacteria for Europe. Supported by the Public Health Laboratory Service.	http://www.ukncc.co.uk http://www.ukncc.co.uk/html/members/nctc/nctc_info.htm http://www.phls.co.uk/labservices/nctc/accessions.htm
		NCIMB Ltd., National Collection of Industrial, Marine and Food Bacteria Ltd., (formerly NCIMB and NCFB), National Collection of Food Bacteria) Aberdeen, Scotland	Includes 3800 accessions of general industrial and scientific significance, (actinomycetes and other bacteria, plasmids, and phages) and 1500 marine bacteria. Originally funded by Ministry of Agriculture, Fisheries and Food. Patent depository. Identification, service, and contract work.	http://www.ncimb.co.uk and www.ukncc.co.uk/ncimb.html
		National Collection of Food Bacteria) Aberdeen, Scotland	About 2000 bacteria of significance to food and dairying. A patent and safe depository. Originally funded by Ministry of Agriculture, Fisheries and Food, Institute of Food Research and is now affiliated with NCIMB, Ltd.	
		NCYC, National Collection of Yeast Cultures, Institute of Food Research, Norwich	Includes brewing yeast strains, genetically defined strains of <i>Saccharomyces cerevisiae</i> and <i>Schizosaccharomyces pombe</i> , and general yeast strains, totaling over 2700 nonpathogenic yeasts. A patent and safe depository. Performs yeast identification services. Member of the European Culture Collections Organization (ECCO) and the WFCC.	http://www.ifrn.bbsrc.ac.uk/NCYC
		NCPE, National Collection of Pathogenic Fungi, London	Has 1500 human and animal pathogenic fungi and performs identification and contract research. Supported by the Public Health Laboratory Service.	http://www.ukncc.co.uk/html/members/Ncpf/ Ncpf_info.htm
		NCWRF, National Collection of Wood Rotting Fungi in Watford	Over 500 cultures of ~300 species of wood-rotting basidiomycetes. Funded by the Department of the Environment. Managed by CABI-Bioscience.	As above, except /ncwrf/ncwrf_info.html
		NCPPB, National Collection of Plant Pathogenic Bacteria, Harpenden	Has 3000 phytopathogenic bacteria, representing a wide range of hosts and locations for species causing most of the known bacterial plant diseases, and has some bacteriophages as well. Funded by the Ministry of Agriculture, Fisheries and Food. Provides information, identification, and contract services.	www.ncppb.com
		See also CABI.Bioscience (IMI), RCR, and IACR collections	Classified in this table as Other—comprehensive, fungal— <i>Rhizobium</i> , RCR; plant pathogens, IACR.	
		CCAP, Culture Collection of Algae and Protozoa	Had its origins with the early culture collections, moving from Prague to England in the 1920s (see early collections section in text),	http://www.ife.ac.uk/ccap and http://www.ukncc.co.uk/html/members/ccap/ccap_info.htm

TABLE 24.1 *Continued*

Type	Country	Designation	Description	Web URL
National consortium, comprehensive	France	CNCM, National Collection of Cultures of Microorganisms	undergoing development at Cambridge University and later moving to two sites—the freshwater algae and all protozoa to the Institute of Freshwater Ecology (IFE) Windermere Laboratory at Ambleside and the marine algae to Dunstaffnage Marine Laboratory (DML) in Scotland. Approximately 2000 strains of algae and protozoa. A patent depository. Established in 1976 by French Ministerial authorities. Housed in the Pasteur Institute. A patent and safe depository. Coordinates activities of the specialized collections of the Pasteur Institute. Member collections include the CIP (see early collections section in text and bacterial type in this table), which incorporates the <i>Pasteurella</i> laboratory collection, the Pasteur Institute collections of cyanobacteria (see PCC under collections of algae, protozoa, and cyanobacteria), <i>Rhodococcus</i> , <i>Gordonia</i> , <i>Lactobacillus</i> , coryne forms, and <i>Pasteurella</i> , as well as fungal, viral, and animal cell collections. Member of the World Federation for Culture Collections and the European Culture Collections Organization.	http://www.pasteur.fr/Bio/RAR96/Colloq.html
National consortium, comprehensive	Belgium	BCCM, Belgian Coordinated Collections of Microorganisms. Includes the following:	Consortium of four research-based collections, containing 50,000 documented strains of bacteria, filamentous fungi, and yeasts, and over 1500 plasmids. Supported by the Belgian Federal Office for Scientific, Technical, and Cultural Affairs. Patent and safe deposit services as well as contract research and training.	http://www.belspo.be/bccm , search at http://www.belspo.be/bccm/db/index.htm
		BCCM/MUCL, the Mycological Collection of the Catholic University of Louvain	Originated with the earliest collections (see early collections section of text). Holds 25,000 strains of fungi and yeast, including representatives of over 3300 species of zygomycetes, ascomycetes, hyphomycetes, and basidiomycetes. Focuses on agro-industrial cultures. Also holds a mycological herbarium of 40,000 fungal specimens. Undertakes research in systematic and applied mycology and provides software for yeast identification.	http://www.belspo.be/bccm/mucl.htm#main
		BCCM/LMBP, the Plasmid and cDNA Collection, University of Ghent	Includes plasmids that replicate in prokaryotic (<i>E. coli</i> and <i>Lactobacillus</i>) and eukaryotic (yeast, animal cell) hosts and 10 cDNA libraries.	http://www.belspo.be/bccm/lmbp.htm#main
		The BCCM/LMG Bacterial Collection, University of Ghent	Holds over 16,000 strains representative of 1300 species, subspecies, or pathovars, with emphasis on phytopathogenic bacteria and species of medical and veterinary significance. Also has marine <i>Vibrio</i> species and strains of some biotechnological interest.	http://www.belspo.be/bccm/lmg.htm#main
		The BCCM/IHEM Collection of Biomedical Fungi and Yeasts, Brussels	A collection of filamentous and yeast fungi of public health and environmental interest, containing over 6500 strains of human and animal pathogenic and allergenic species. These include specific disease isolates, e.g. 500 <i>Aspergillus fumigatus</i> and 300 <i>Candida albicans</i> isolates. Located at the Scientific Institute of Public Health—Louis Pasteur in Brussels	http://www.belspo.be/bccm/ihem.htm#main
National consortium, comprehensive	The Netherlands	CBS, The Centraal Bureau voor Schimmelcultures	The CBS collection and NCCB, described below, are separate units of the organizational structure of the CBS, an institute of the Royal Netherlands Academy of Arts and Sciences.	http://www.cbs.knaw.nl
		CBS, the Centraal Bureau voor Schimmelcultures Collection, Baarn and Delft	See early collections section of text. Currently includes separate collections and databases for filamentous fungi in Baarn (over 28,000 strains) and yeasts in Delft (4500 strains), with the IGC collection of 1250 yeast strains in Oeiras, Portugal, also included in the database, and a database for taxonomic and nomenclatural data for	http://www.cbs.knaw.nl , http://www.cbs.knaw.nl/search_fdb.html , http://www.cbs.knaw.nl/yeast/webc.asp http://www.cbs.knaw.nl/fusarium/database.html ; and

TABLE 24.1 *Continued*

Type	Country	Designation	Description	Web URL
			<i>Fusarium</i> and the Aphyllophorales. One of the largest collections of fungi in the world, totaling over 35,000 strains, its goal is to have representatives of all fungal groups that can be cultured. Plans to integrate yeasts and fungi into one institute. Serves as the Dutch node of MINE, the Microbial Information Network of Europe, an EC-sponsored network of European collections. Performs identification and patent deposit services.	http://www.cbs.knaw.nl/aphyllo/database.html
		NCCB, Netherlands Culture Collections of Bacteria, Utrecht	Merger of the Bacterial Collection of Kluyver Laboratory of Microbiology at the Technical University of Delft (Kluyver Institute of Biotechnology), the LMD, containing over 4500 strains, and the Phabagen Collection (see Microbial Genetic Stock Centers) at the University of Utrecht. Participant in CABRI. Patent and safe depository, taxonomic research, identification, and consultation services.	http://www.cbs.knaw.nl/nccb/ http://www.cbs.knaw.nl/nccb/about.htm
National consortium, comprehensive	Germany	DSMZ, Deutsche Sammlung von Mikroorganismen und Zellkulturen, Braunschweig	Founded in 1969 as the national culture collection of Germany, part of the Gesellschaft für Strahlenforschung in Munich. Moved to the Gesellschaft für Biotechnologische Forschung in Braunschweig, in 1988 became a private company, and in 1996 became an independent non-profit organization supported by the Federal Ministry of Research and Technology and the State Ministries. Holds over 8700 bacteria and archaea, 300 plasmids, 100 phages, 2300 filamentous fungi, 500 yeasts, 700 plant viruses, as well as plant, human, and animal cell lines. Serves as a safe and patent repository, and performs teaching, service, and identification functions. On-line searchable databases for microorganisms, cell lines, and plasmids, as well as a bacterial nomenclature database.	http://www.dsmz.de , http://www.dsmz.de/bactnom/bactname.htm
National consortium, comprehensive	Czech and Slovak Republics	Czech Federation of Culture Collections The Czech Collection of Microorganisms, Brno	Includes a number of microbial collections, the larger collections listed below. Member of the WFC and ECCO. Established at the J. E. Purkyne University in 1963, based on the bacterial collection of the university begun in 1957 and merged with the Culture Collection of the Institute of Microbiology, of the Czechoslovak Academy of Science in Prague. Includes over 2000 strains (representing more than 170 genera and 600 species) of bacteria, over 300 strains of fungi, mycoplasmas, and viruses, particularly animal pathogens and organisms of interest to food microbiology, medicine, education, agriculture, and industry. Performs identification and consultation services and serves as a safe repository. Member of the WFCC.	http://www.natur.cuni.cz/fccm
		The Czech Culture Collection of Fungi (CCF) at Charles University, Prague CCBAS, the Culture Collection of Basidiomycetes	Combined the collections of the Biological Institute of the Czechoslovak Academy of Sciences and the Charles University Botany Department research collection in 1964–1965. Approximately 1600 strains of zygomycetes and ascomycetes. Founded in 1959 and contains 630 strains and 253 species, including some rare species.	http://www.natur.cuni.cz/fccm/#ccf and http://wdcm.nig.ac.jp/CCINFO/CCINFO.xml? 182 http://www.biomed.cas.cz/ccbas/fungi.htm
National consortium, comprehensive	Poland	PCM, Polish Collections of Microorganisms	Combines several individual collections at the Hirsfeld Institute of the Polish Academy of Sciences, Wrocław. These include the DMVB and the CRS, Collection of <i>Rhizobium</i> Strains, in Pulawy, the Industrial Microorganism collection in Lodz and Warsaw, the Dairy Cultures collection in Olsztyn, the National <i>Salmonella</i> Centre in Gdynia-Redlowo, and the Research and Development Center for Biotechnology in Warsaw. Represents	http://wdcm.nig.ac.jp/CCINFO/CCINFO.xml? 106

National consortium, comprehensive	Russia	VKM, the All-Russian Collection of Microorganisms, Institute of Biochemistry chemistry and Physiology of Microorganisms	a wide range of bacteria, yeasts, and filamentous fungi, which are searched for and described from a single Web site. Merger in 1980 of the Institute of Microbiology's collection of yeast cultures of V. Kudryavtsev begun in the 1930s and the Institute of Biochemistry and Physiology's collections of microorganisms begun in 1968. Over 9000 strains, encompassing 3000 species of 650 genera, of bacteria, actinomycetes, filamentous fungi, and yeast. Includes genetically modified strains of <i>E. coli</i> and yeast as well as a few genetic derivatives of <i>Agrobacterium tumefaciens</i> , <i>Bradyrhizobium japonicum</i> , and <i>Streptomyces galilaeus</i> . Russian Academy of Sciences, Pushchino, Moscow region.	Searches and information via WDCM at http://www.vkm.ru and (www.vkm.ru) and http://wdcm.nig.ac.jp/CCINFO/CCINFO.xml? 342
National, comprehensive	Ukraine	VKIM, All-Russian Collection of Industrial Microorganisms IMV, Zabolotny Institute of Microbiology and Virology Collection	Institute of Genetics and Selection of Microorganisms, Moscow. Sponsored by the Academy of Sciences in Kiev.	See MSDN
National, comprehensive	Belarus	INMIB Collection of the Institute of Microbiology	Academy of Science of Belarus, Minsk.	http://www.ac.by/organizations/institutes/inbio.html#off3578
National, comprehensive	Bulgaria	NBIMCC, National Bank for Industrial Microorganisms and Cell Cultures, Sofia	Founded in 1983, encompasses the Bulgarian Type Culture Collection, and includes fungi and yeasts, bacteria and actinomycetes, plasmids, viruses, and cell lines.	http://wdcm.nig.ac.jp/CCINFO/CCINFO.xml? 135
National, comprehensive	Hungary	NCIM, National Collection of Agricultural and Industrial Microorganisms, Budapest	At the University of Horticulture and Food Industry Includes over 1600 strains of bacteria, yeasts, and fungi. It was established in 1974 and is a patent and safe depository and performs purification, identification, consultation, and training services. Member of the WFCC and ECCO.	http://ncaim.kee.hu . http://wdcm.nig.ac.jp/CCINFO/CCINFO.xml? 485
National, comprehensive	India	NCIM, National Collection of Industrial Microorganisms, Pune	A collection of over 100 bacteria, nearly 2000 fungi and yeasts, and a few algae and protozoa. National Chemical Laboratory in Pune, sponsored by the Council for Scientific and Industrial Research.	http://kelvin.ncl.rcs.in/ncim
National, comprehensive	India	ITCC, the Indian Type Culture Collection, New Delhi	Division of Mycology and Plant Pathology, Indian Agricultural Research Institute.	http://wdcm.nig.ac.jp/CCINFO/CCINFO.xml? 430
National, comprehensive	India	MTCC, Microbial Type Culture Collection and Gen Bank, Chandigarh	Established 1986 at the Institute of Microbial Technology. Actinomycetes, bacteria, yeast, fungi, plasmids	http://imtech/ernet.in/mtcc See also http://wdcm.nig.ac.jp/CCINFO/CCINFO.xml? 773
National consortium, comprehensive	China	CCCCM, the China Committee for Culture Collections of Microorganisms	Provides search capability by name or keyword for databases encompassing the following three collections as well as others. It also provides a national node of the MSDN that allows querying of some general and many specialized collections in many countries (CCCCM). Oversees the following three collections:	See Micro-Net of China http://www.im.ac.cn . Search collections at http://www.im.ac.cn/database/catalogs.html . MSDN node: http://www.im.ac.cn/msdn.html
		CCCM, the Center for Culture Collection of Microorganisms, Beijing	Institute of Microbiology, Chinese Academy of Science. Includes 1900 yeasts, 5500 other fungi, 2200 bacteria, and 1400 actinomycetes; also included are the type culture collection of China and patent strain repository.	http://www.im.ac.cn/en/tcfmr.php http://www.micronet.cn http://im.ac.cn/sklomr
		CCVCC, the China Center for Virus Culture Collection	Collects, preserves, classifies, and studies viruses, now numbering 600, including insect, plant, bacterial, and animal viruses. Chinese Academy of Sciences, Wuhan Institute of Virology, established in 1979.	http://www.micronet.cn/institutes/ccvcc/ccvcc.html
		ACCC, the Agricultural Culture Collection of China, Beijing	The ACCC holds more than 2000 strains of bacteria, actinomycetes, fungi, rhizobia, and edible fungi. Chinese Academy of Agricultural Sciences, Beijing, established in 1980.	http://www.micronet.cn/institutes/acc/acc.html

TABLE 24.1 *Continued*

Type	Country	Designation	Description	Web URL
National, comprehensive	Thailand	TISTR, the Thailand Institute of Scientific and Technological Research Collection	Linked to WDCM and can be queried at the Web site shown. The Tropical Database of Thailand is also cited by WDCM as a TISTR project. Supported by the Ministry of Science, Technology and Environment of Thailand.	http://wdcm.nig.ac.jp/CCINFO/CCINFO.xml? 383
National consortium, comprehensive	Japan	JFCC, Japan Federation of Culture Collections IAM Culture Collection, Institute of Applied Microbiology, University of Tokyo The Japan Collection of Microorganisms (JCM) in the Institute of Physical and Chemical Research (RIKEN)	Maintains a search capability for the various collection databases for bacteria, fungi, viruses, and algae. Founded in 1953 and in 1993 reorganized in the IMCB (Institute of Molecular and Cellular Biosciences) to broaden coverage to higher organisms and their cultured cells. The microbial collection contains over 3400 strains of bacteria, yeasts, filamentous fungi, and algae. Has since 1980 distributed microorganisms from a collection that includes over 3500 strains of bacteria, including actinomycetes, 2000 strains of fungi, including yeasts, and a hundred strains of archaea. Collections such as the KCC Culture Collection of Actinomycetes, Kaken Chemical Co., Tokyo, have transferred their holdings to the JCM. On-line catalog allows searching by scientific names or key words and contains information about strain history, taxonomy, reference citations, and cultivation conditions. Database also can be used to search for strains of bacteria, fungi, and yeasts, bacteriophages and other viruses, algae, and protozoa in Japan and elsewhere.	http://wdcm.nig.ac.jp/wdcm/JFCC.html http://www.iam.u-tokyo.ac.jp/misyst/ColleBOX/IAMcollection.html http://www.jcm.riken.go.jp/JCM/aboutJCM.html , http://wdcm.nig.ac.jp/wdcm/JFCC.html
National, comprehensive	Taiwan	National Institute of Genetics Cloning Vector and <i>E. coli</i> Collections The CCRC, Culture Collection and Research Center	Provides vectors of <i>E. coli</i> that can be stored stably as purified DNA. It also has the <i>E. coli</i> Genetic Resources collection—see bacterial collections in this table. Founded by the Food Industry Research and Development Institute in Hsinchu, Taiwan, in 1982. Began with food microbiology and expanded to serve the interests of industry, agriculture, medicine, environmental research, education, and biotechnology. Includes bacteria, yeasts, filamentous fungi, bacteriophages, and plasmids and phage vectors.	http://www.shigen.nig.ac.jp/cvector/cvector.html http://wdcm.nig.ac.jp/CCINFO/CCINFO.xml? 59
National consortium, comprehensive	Indonesia	Various collections, mostly governmental and university	Collections in Indonesia are listed at the WDCM Website shown. Include yeasts, algae, lichens, protozoa, fungi, bacteria, and viruses.	http://wdcm.nig.ac.jp/indonesia.html
Other comprehensive	Australia	UNSWCC, the University of New South Wales Culture Collection The Division of Food Research, CSIRO, in New South Wales The University of Queensland Microbial Culture Collection in Brisbane Other collections	Established in 1969. Provides catalogs of algae and protozoa, fungi and yeast, and bacteria. Has a collection of 3000 fungi and 100 yeasts. Has over 3500 cultures of bacteria and also has algae, fungi, yeasts, and viruses. It provides identification and training and patent deposit services. Thirty other culture collections in Australia are at the Web address shown.	http://www.micro.unsw.edu.au/cult.html http://wdcm.nig.ac.jp/CCINFO/CCINFO.xml? 18 http://wdcm.nig.ac.jp/CCINFO/CCINFO.xml? 13 http://wdcm.nig.ac.jp/hpcc.html
National, comprehensive	New Zealand	The International Collection of Microorganisms from Plants, Auckland The New Zealand Reference Culture Collection of Microorganisms	Includes bacteria and fungi, with primary emphasis on plant pathogens. Sponsored by the New Zealand Dairy Research Institute.	http://wdcm.nig.ac.jp/CCINFO/CCINFO.xml? 589 and http://nzfungi.landcare.research.co.nz/icmp/search_cultures.asp http://wdcm.nig.ac.jp/CCINFO/CCINFO.xml? 318

(Continued overleaf)

TABLE 24.1 (Continued)

Type	Country	Designation	Description	Web URL
		Other reference culture collections	Including those in the Communicable Disease Centre in Porirua, the Animal Research Centre in Wellington, the New Zealand Forest Research Institute Culture Collection in Rotorua, the International Collection of Microorganisms from Plants, DSIR, Auckland, and the Institute of Environmental Science and Research, Medical Section, in Porirua. These and other New Zealand collections are described in records accessible from the WDCM.	see http://wdcm.nig.ac.jp/CCINFO/CCINFO.xml? with suffixes 62, 457, 335, 764 and 376
National consortium, comprehensive	Brazil	Base de Dados Tropical	Although culture collections remain separate, the Base de Dados Tropical presents Brazilian National Catalogs of Strains for Algae, Bacteria, Filamentous Fungi and Yeasts, Protozoa, and Viruses, which allows querying across collections varying from one (for viruses) to eighteen (for bacteria) individual collections in Brazil. Maintains a separate database for Colecao de Culturas Tropical Organisms and services and for an Entomopathogenic Fungi Databank and List of Bacterial Cultures of the Biological Institute in Sao Paulo, IBSBF.	http://www.bdt.org.br/
National collection	Mexico	CENACUMI, National Center for Microbial Cultures, UNAM, Mexico City	Agricultural, industrial, medical, and marine organisms for biotechnology, food, and environmental sciences. Bacteria, fungi, yeasts, cell lines, and viruses. Patent depository	http://wdcm.nig.ac.jp/CCINFO/CCINFO.xml? 757. See also other collections wdcm.nig.ac.jp/hpcc.html and .xml? 449
National consortium	Canada	CMGRIS, the Canadian Microbial Genetic Resources Information System	The goal is to develop a comprehensive information system for all microbial genetic resources, bacteria, fungi, yeasts, viruses, algae, and protozoa. The first of the collections to be presented by this information system was the Canadian Collection of Fungal Cultures, CCFC. See below.	http://cis.agr.ca/brd/cccl/cccmicro.html
		CCFC, the Canadian Collection of Fungal Cultures	Has over 10,000 strains representing 2500 species and is the primary repository for fungi in the Agriculture and Agri-Food Canada Research Branch and a patent repository.	http://cis.agr.ca/brd/ccc
		UAMH, the University of Alberta Microfungus Collection and Herbarium	Has over 9400 strains. Established in 1960 and supported by the Natural Sciences and Engineering Research Council of Canada and the University of Alberta Devonian Botanic Garden. A Canadian repository for fungus cultures of scientific or industrial importance, including all kinds of fungi, but specializing in ascomycetous and hyphomycetous microfungi.	The collection can be searched at http://www.devonian.ualberta.ca/uamh/index.html-ssi
		Other Canadian collections	Information on many other Canadian collections, including university, Forest Service, and public laboratory collections, can be found at the Web address shown.	http://wdcm.nig.ac.jp/hpcc.html
National consortium, comprehensive	United States	USDA/ARS collections, including NCAUR (NRRL), ARSEF, National <i>Rhizobium</i> Germplasm Resource Center	See text section on early collections for descriptions. Also in this table, see section on Fungi. Over 80,000 strains in collections of filamentous fungi, yeasts, bacteria, non-pathogenic to animals or humans. The ARSEF and National <i>Rhizobium</i> Center have entomopathogenic and rhizobium collections. Patent depository, research programs, identification services.	http://nrri.ncaur.usda.gov , http://www.ars-grin.gov/nmg , http://www.ppru.cornell.edu/Mycology/ARSEF_Culture_Collection.html
Other comprehensive	United States	ATCC, American Type Culture	See text section on early collections. Holds over 14,000 bacterial strains, 500 viral strains, 26,000 strains of 6500 yeast and fungal species, as well as protozoa, hybridomas, probes, and clones.	http://www.atcc.org
Other comprehensive	UK location, Sponsored by 34 CAB countries	IMI, International Mycological Institute Culture Collections, Surrey Cabi-Bioscience UK Centre	Described in the early collections section of the text. The bacterial collection and the fungal/yeast collection of 16,500 strains can be searched at the Website shown. See also entry under Filamentous fungi and yeast section of this table. Now part of CABI-Bioscience	http://www.cabi-Bioscience.org/Html/ReferenceCollections.htm

TABLE 24.1 *Continued*

Type	Country	Designation	Description	Web URL
Other comprehensive, primarily bacterial	Sweden	CCUG, Culture Collection, University of Goteborg	Founded in 1968, holds 40,000 strains of bacteria also some yeast and fungi. In 1981, the CCUG was a joint founder of the ECCO, European Culture Collections Organization, and in 1984 it became part of the WDCM. Since 1991, a participant in the MINE project, Microbial Information Network Europe. Includes the genera <i>Helicobacter</i> , <i>Fusobacterium</i> , <i>Bilophila</i> , <i>Haemophilus</i> , <i>Neisseria</i> , <i>Campylobacter</i> , <i>Streptococcus</i> , <i>Actinomyces</i> , <i>Aeromonas</i> , <i>Vibrio</i> , <i>Bacillus</i> , <i>Enterococcus</i> , <i>Staphylococcus</i> , various members of Enterobacteriaceae, and others. Performs identification of bacterial species and maintains a database of bacterial names.	http://www.ccug.gu.se
Other comprehensive	Finland	HAMBI, the Culture Collection, University of Helsinki	Strains of bacteria, filamentous fungi, and yeasts, ~2400. Department of Applied Chemistry and Microbiology.	http://honeybee.helsinki.fi/MMKEM/hambi
Other comprehensive	Japan	IFO, Culture Collection of the Institute for Fermentation, Osaka	A large collection of over 4400 bacteria, 7700 fungi, and 3000 yeasts as well as animal cell lines and viruses. Nonprofit organization.	http://www.nacsis.ac.jp/ifo/microorg/microorg.htm , http://wdcm.nig.ac.jp/CCINFO/CCINFO.xml?wdcm191
Bacterial Bacterial	Russia	IBSO Siberian Culture Collection of Luminous Bacteria	Institute of Biophysics, Krasnoyarsk. Dates to 1970s. Expeditions in ocean waters and other waters and subsequent studies of luminescent bacteria with benthic organisms and in particular with coral reef inhabitants.	http://panizzi.shef.ac.uk/msdn/ibso
Bacterial	Russia	KMMGU Russia Database of Collections in Lomonosov State University, Moscow	Department of Microbiology, Lomonosov State University.	http://panizzi.shef.ac.uk/msdn/kmmgu
Bacterial	US, UK, The Netherlands, and others	Various consortia and national collections	See Comprehensive section of this table.	See URLs in Comprehensive section, e.g. NCAUR, ATCC, NCTC, NCIMB, NCFP, NCCB
Bacterial	Russia	VKM	See Comprehensive national collections section of this table.	See URLs in Comprehensive section
Bacterial	France	CIP, The Collection of the Bacterial Strains of Institut Pasteur	See National collections, CNCM. Incorporates the <i>Pasteurella</i> laboratory collection, the Pasteur Institute collections of cyanobacteria (see also PCC under Algae, protozoa, and cyanobacteria section of this table), <i>Rhodococcus</i> , <i>Gordonia</i> , <i>Lactobacillus</i> , coryneforms, and <i>Pasteurella</i> . Collecting began in 1891–1901. See text section on early collections.	http://www.pasteur.fr/applications/CIP Also Centre des Yersinia and CIPT, wdcm.nig.ac.jp/hpcc.html
Bacterial	Belgium	BCCM/LMG Bacterial	See National consortium, comprehensive section of this table.	http://www.belspo.be/bccm/lmg.htm#main
Primarily bacterial, some fungal and yeast	Argentina	CCM-A, Collection of Microbiological Cultures, University of Buenos Aires	Has about 900 bacteria and about 50 fungal and yeast cultures and serves as a patent and safe depository and center for identification, training, and consultation.	http://wdcm.nig.ac.jp/CCINFO/CCINFO.xml? 29
Primarily bacterial	Cuba	Collecion de Cultivos Finlay and CGEB Culture Collections of Microorganisms	Instituto Finlay, Ciudad de la Habara and Center of Genetics, Engineering and Biotechnology, Havana	http://wdcm.nig.ac.jp/CCINFO/CCINFO.xml? 771 and 772
Bacterial and fungal	Argentina	The National University of Cordoba, Laboratory of Microbiology	Maintains a specialized collection of about 200 strains of bacteria and fungi, which can be searched via MSDN.	http://panizzi.shef.ac.uk/msdn/
Bacterial—methanogens	United States	OCM, the Oregon Collection of Methanogens and Subsurface Microbial Culture Collection (DOE)	Approximately 150 strictly anaerobic methanogens, gens, primarily archaeobacteria, and 50 nonmethanogens. At the Oregon Graduate Institute Department of Environmental Sci. and Engineering, which also maintains Subsurface Microbial Culture Collection. Offers strains and cell masses or DNA of certain strains. Main deep subsurface collection, Florida state.	http://methanogens.pdx.edu and http://methanogens.pdx.edu/smcc/ http://ocean.fsu.edu

(Continued overleaf)

TABLE 24.1 *Continued*

Type	Country	Designation	Description	Web URL
Bacterial—lactic acid and other	Japan	NRIC, the Nodai Research Institute Culture Collections, Tokyo University of Agriculture	See also entry under Fungi in this table. Food-fermentation microorganisms. 2500 lactic acid bacterial (also 400 other bacteria, 1400 yeast cultures) Member Japan Society for Culture Collections	http://wdcm.nig.ac.jp/CCINFO/CCINFO.xml? 747 http://wdcm.nig.ac.jp/wdcm/JFCC.html
Bacterial—Antarctic	Australia	ACAM, the Australian Collection of Antarctic Microorganisms	University of Tasmania, Heterotrophic bacteria collected from Antarctica and subantarctic islands and Southern Ocean. Established 1986.	http://www.antcrc.utas.edu.au/antcrc/micropro/acaminfo.html
Bacterial— <i>Escherichia</i> and <i>Klebsiella</i>	Denmark	Statens Serum Institute, WHO International <i>Escherichia</i> Centre	Sponsored by the World Health Organization of the UN, maintains ~400 serovars. Collaborating Centre for Reference and Research on <i>Escherichia</i> and <i>Klebsiella</i> . Performs serotype identification services as well as providing cultures. Copenhagen.	Artellerivej 5,300 Copenhagen S, Denmark Fax: 4532 683868
Bacterial— <i>E. coli</i>	United States	ECOR, the <i>E. coli</i> Reference Collection and DEC and other STEC (Shiga toxin-producing <i>E. coli</i>) reference collections	The ECOR, established by H. Ochman and R. Selander (1984) from human and animal hosts to represent variation in O and H serotypes, the DEC collection of diarrheagenic strains, and other STEC reference collections at Michigan State STEC center	http://www.shigatox.net/stec , http://foodsafes.msu.edu/whittam/ecor , and http://shigatox.net/cgi-bin/deca http://bacillus.biosci.ohio-state.edu
Bacterial— <i>Bacillus</i> , genetic	United States	BGSC, <i>Bacillus</i> Genetic Stock Center, Ohio State University	See bacterial genetic stock centers section of text. Publishes genetic map. <i>B. subtilis</i> and other <i>Bacillus</i> species in addition to strain distribution.	http://cgsc.biology.yale.edu
Bacterial— <i>E. coli</i> , genetic	United States	CGSC, <i>E. coli</i> Genetic Stock Center, Yale University	See bacterial genetic stock centers section of text. Publishes genetic map, registers gene symbols and allele numbers in addition to strain distribution.	http://cgsc.biology.yale.edu
Bacterial— <i>E. coli</i>	Japan	NIG, National Institute of Genetics	See Bacterial Genetic Stock Centers section of text. Approximately 4000 strains and over 400 cloning vectors	http://shigen.lab.nig.ac.jp/ecoli/strain http://www.shigen.lab.nig.ac.jp/cvector/cvector.html
Bacterial— <i>Salmonella</i> , genetic	Canada	SGSC, <i>Salmonella</i> Genetic Stock Centre, University of Calgary	See bacterial genetic stock centers section of text. Publishes genetic map, registers gene symbols and allele numbers in addition to strain distribution.	http://www.acs.ucalgary.ca/~kesander
Bacterial— <i>Salmonella</i>	Poland	National <i>Salmonella</i> Center	See National, comprehensive section of this table, PCM	http://wdcm.nig.ac.jp/CCINFO/CCINFO.xml? 784
Bacterial— <i>Rhizobium</i>	Poland	CRS Collection of <i>Rhizobium</i> strains, Pulawy	See National, comprehensive section of the table, PCM, and other listings in WDCM.	http://wdcm.nig.ac.jp/hpcc.html http://www.iacr.bbsrc.ac.uk/ppi/cultures and wdcm.nig.ac.jp/CCINFO/CCINFO.xml? 607
Bacterial— <i>Rhizobium</i>	United Kingdom	RCR Rothamstead Collection of <i>Rhizobium</i> , Harpenden and Welsh WPBS	Collection of <i>Rhizobium</i> of the Soil Microbiology Department.	http://www.ars.usda.gov/is/np/systematics/rhizobium.htm
Bacterial— <i>Rhizobium</i>	United States	USDA/ARS National Collection of <i>Rhizobium</i>	Part of the USDA/ARS National <i>Rhizobium</i> Germplasm Research Center, combining USDA/ARS collections with the Lipha-Tech, Boyce Thompson Institute, University of Minnesota ARS Collection, the University of São Paulo, Brazil Collection, and the Centro Internacional de Agricultura Tropical (CIAT) collection in Cali, Colombia.	http://www.ars.usda.gov/is/np/systematics/rhizobium.htm
Bacterial—alkantrophic	Russia	IEGM, Institute of Ecology and Genetics of Microorganisms, Moscow	Regional specialized collection of alkanotrophs (which assimilate <i>n</i> -alkanes gases and liquid hydrocarbons as carbon and energy source) with 400 species, 1000 strains. Includes mycobacteria and actinomycetes— <i>Rhodococcus</i> , <i>Gordona</i> , <i>Micrococcus</i> , <i>Brachybacteria</i> species. Collecting began in 1975 for studies of bio-indicators of gas and oil fields and pollution. Russian Academy of Science, Urals Branch.	http://wdcm.nig.ac.jp/wdcm/IEGM_readme.html and CCINFO/CCINFO.xml? 768
Fungi, including yeasts				
Plant pathogens	United Kingdom	The Institute of Arable Crops—Rothamstead (IACR) Plant Pathology Culture Collections	Specialized collection that holds over 600 soil-borne fungi from around the world, with particular emphasis on cereal root pathogens of the Gaeumannomyces-Phialophora complex of fungi. The GPDATA records include collecting information and pathogenicity tests, and queries	http://www.rothamsted.bbsrc.ac.uk/ppi/cultures

TABLE 24.1 *Continued*

Type	Country	Designation	Description	Web URL
Fungi	Czech Republic	FCCM (CCF) and CCBAS	based on name or origin of culture can be entered from the Website. See National, comprehensive section of this table.	http://www.biomed.cas.cz/ccbas/fungi.htm , and http://www.natur.cuni.cz/fccm
Fungi	Canada	CCFC and UAMH	See National consortium section of this table.	http://sis.agr.gc.ca/brd/ccfcccintro.html and http://www.devonian.ualberta.ca/uamh/index.html-ssi
Filamentous fungi and yeasts	Belgium	The Mycological Collection of the Catholic University of Louvain, MUCL, and IHEM	<i>Penicillium</i> , <i>Aspergillus</i> , hyphomycetes and other fungi, and yeasts. See National Consortium section of this table, Belgium, BCCM/MUCL and BCCM/IHEM.	http://www.belspo.be/bccm/
Filamentous fungi and yeasts	The Netherlands	See National, comprehensive section of table, CBS	Note particularly filamentous fungi in Baarn, yeasts in Delft and Oeiras, Portugal, and taxonomic and nomenclature databases for <i>Fusarium</i> and Aphyllophorales.	http://www.cbs.knaw.nl/search_fdb.html and http://www.cbs.knaw.nl/yeast/webc.asp
Filamentous fungi and yeasts	United Kingdom	See National consortium section, NCPF, NCYC, NCWRF, IACR	Note particularly NCPF for pathogenic fungi, NCYC for yeast cultures, NCWRF for wood-rotting fungi, and the NCPPB and IACR for plant pathogens.	http://dtiinfo1.dti.gov.uk/bioguide/culture.htm
Filamentous fungi and yeasts	Multinational, in UK	IMI, International Mycological Institute	See early collections section of text. Holds 16,500 strains. Part of CAB International, supported by 32 governments.	http://www.cabi-bioscience.org/html/grc.htm
Filamentous fungi and yeasts	Sweden	UPSC, Mycoteket, Uppsala University	Over 3000 fungal cultures. See early collections section of text.	http://www.hotel.uu.se/evolmuseum/mykotek/index.htm
Fungi—mycorrhizal	United States	The International Culture Collection of Vesicular–Arbuscular Mycorrhizal Fungi (INVAM) at West Virginia University	Holds and distributes strains representing more than 60 of the 154 known mycorrhizal species and has other strains yet to be identified. NSF-supported collection of vesicular and vesicular arbuscular mycorrhizal fungi, originated with N. Schenck at the University of Florida in 1985, moved to West Virginia University in 1990, combining with J. Morton's collection. Over 1100 cultures, including species in the genera <i>Acaulospora</i> , <i>Entrophospora</i> , <i>Gigaspora</i> , <i>Glomus</i> , and <i>Scutellospora</i> . Website information on species, nomenclature, methods, and services; querying by name or site characteristic.	http://invam.caf.wvu.edu/ Links to general mycorrhizal information are also maintained (http://mycorrhiza.ag.utk.edu and http://invam.caf.wvu.edu/otherinfo/Articles/articles.htm)
Fungi—mycorrhizal (arbuscular)	European	BEG, the European Bank of the Glomales	European "Stock Center without Walls," with isolates representing temperate, tropical, and polar representatives of Glomales species. Database of these European endomycorrhizal collections can be queried by genus, species, continent, country, biome, or associated plant.	http://www.kent.ac.uk/bio/beg
Fungi—entomopathogenic	United States	ARSEF, USDA-ARS Collections of Entomopathogenic fungi, Ithaca, New York	See early collections section of the text and National collection section of this table.	http://www.ppru.cornell.edu/Mycology/ARSEF_Culture_Collection.htm
Fungi (including yeast)	United States	USDA/ARS/NCAUR Peoria, Illinois	Extensive holdings. See early collections section in text. Largest U.S. yeast collection (including Antarctic Marine Yeast Collection, described below). Also <i>Aspergillus</i> and <i>Penicillium</i> collection and collection of other filamentous fungi. Research, identification services, and patent depository.	http://nrml.ncaur.usda.gov
Marine yeasts		The Antarctic Marine Yeasts Collection	Established in 1989 to preserve 3000 strains of yeast isolated and studied during the 1960s from the Antarctic, South Pacific, and Indian oceans. Contributed by J. Fell of the University of Miami to NCAUR Yeast Collection.	See http://nrml.ncaur.usda.gov
Yeast	United States	The Phaff Collection of Yeasts and Yeast-like Microorganisms at University of California, Davis	Specialized collection emphasizing microbial diversity in natural habitats. Dedicated in 1996, but its history traces back to wine- and food-related yeasts at the College of Agriculture and Experiment Station and the Food Science Department. In 1939, H. J. Phaff began to develop the collection into a yeast taxonomy and ecology collection.	Website http://www.phaffcollection.com/home.asp

(Continued overleaf)

TABLE 24.1 *Continued*

Type	Country	Designation	Description	Web URL
Filamentous fungi and yeasts, primarily	Slovenia	MZKI, Microbial Culture Collection of the National Institute of Chemistry	Includes over 6000 strains from North and South America, Asia, Australia, and Europe. Formerly the Filamentous Fungi Collection, Kernijski Institute in Ljubljana, now at the National Institute of Chemistry, Hajdrihova. Storage (including bacteria), identification, patent depository, and consultation services.	http://wdcm.nig.ac.jp/CCINFO/CCINFO.xml? 599
Filamentous fungi and yeasts	Australia	See National collection section of table	Comprehensive section of table—National consortium, especially CSIRO collection, New South Wales.	http://wdcm.nig.ac.jp/hpcc.html
Filamentous fungi and yeasts, primarily	Brazil	ESAP, Escola Superior de Agricultura collection in São Paulo	Approximately 1000 cultures of fungi and yeasts and 70 bacteria.	http://wdcm.nig.ac.jp/CCINFO/CCINFO.xml? 720
Filamentous fungi and yeasts	Brazil	URM, Federal University of Pernambuco	Approximately 2000 fungi and yeasts.	http://wdcm.nig.ac.jp/CCINFO/CCINFO.xml? 604
Filamentous fungi and yeasts	Brazil	IOC, Culture Collection of the Instituto Oswaldo Cruz in Rio de Janeiro	Approximately 1400 fungal cultures. Training and consultation services.	http://wdcm.nig.ac.jp/CCINFO/CCINFO.xml? 720
Fungi	Japan	NRIC, the Nodai Research Institute Culture Collection, Tokyo	Tokyo University of Agriculture. Primarily food fermentation microorganisms. Over 1400 yeast cultures and 400 molds. See also bacterial entry in table.	http://wdcm.nig.ac.jp/CCINFO/CCINFO.xml? 747
Fungi	India	DUM, Delhi University, Mycological Herbarium collection	Department of Botany Mycological Herbarium. 200 cultures of fungi. Performs identification services.	http://wdcm.nig.ac.jp/CCINFO/CCINFO.xml? 40
Fungi—Basidiomycetes	India	ITCC, India Type Culture Collection Mushroom Cultures	Indian Agricultural Institute Department of Pathology. Has <i>Agaricus</i> , <i>Auricularia</i> , <i>Lentinus</i> , and <i>Pleurotus</i> species.	http://panizzi.shef.ac.uk/msdn/ and http://wdcm.nig.ac.jp/CCINFO/CCINFO.xml? 430
Fungi	Russia	RIAM, Research Institute of Applied Microbiology, Obolensk	Moscow region, Russian Fungal Collection.	http://panizzi.shef.ac.uk/msdn
Fungi—Basidiomycetes	Russia	Le(BIN) Basidiomycete Collection, St. Petersburg	Komarov Botanical Institute of the Russian Academy of Sciences.	http://panizzi.shef.ac.uk/msdn
Yeast	Russia	MSU, Moscow State University Yeast Database	Department of Soil Microbiology. See also yeast collection within VKM National collection, Comprehensive section of this table.	http://panizzi.shef.ac.uk/msdn
Yeast	Germany	IMET National Kultursammlung von Microorganismen, Jena	Zentralinstitut für Mikrobiologie und Experimentelle Therapie, ZIMET. Also yeasts within DSMZ National Collection.	Available at http://www.dsmz.de
Yeast (also see Comprehensive—other)	Japan	IFO, Culture Collection of the Institute for Fermentation, Osaka	A large collection of over 4400 bacteria, 7700 fungi, and 3000 yeasts as well as animal cell lines and viruses.	http://www.ifo.or.jp/index_e.html
Fungi and yeast	United States	Fungal Genetics Stock Center and Yeast Genetics Stock Center	Described in the text section on early genetic stock centers.	http://www.fgsc.net and http://www.atcc.org/SpecialCollections/YGRRC.cfm and searchcatalogs/Fungi-Yeasts.cfm/
Fungi and yeast	Brazil	Individual Collections	See National consortium section of this table.	
Yeast	Russia	Peterhof Genetic Collection of Yeasts	Described in the text section on early genetic stock centers.	http://wdcm.nig.ac.jp/msdn/peteri.html
Algae, Protozoa, and Cyanobacteria				
Algae, protozoa, and cyanobacteria	United States	UTEX, the Culture Collection of Algae at the University of Texas	Over 2100 strains of primarily freshwater algae. Began at Indiana University in 1954 and moved with Prof. R. C. Starr to Austin in 1976. Supported by the NSF and the University of Texas Organized Research Units. Lists of UTEX cultures and genera can be accessed from the Website, along with information on culture media and links to other collections.	http://www.bio.utexas.edu/research/utex
Algae, protozoa, and cyanobacteria	United Kingdom	CCAP, the Culture Collection of Algae and Protozoa	See early collections section of text and National Consortium—UK entries in this table. Approximately 2000 strains of algae and protozoa at IFE and DML. Patent depository.	http://www.ife.ac.uk/ccap

TABLE 24.1 *Continued*

Type	Country	Designation	Description	Web URL
Algae, protozoa, and cyanobacteria	Czech Republic	CCALA, the Culture Collection of Autotrophic Organisms	Began with early algal collection of Uhlir and Pringsheim in Prague, 1913, and merged in 1979 with the collection of the Institute of Microbiology, Czech Academy of Sciences at Trebon, founded in 1960. See early collections section of text. Over 200 strains of cyanobacteria and over 300 algae, and also has mosses, liverworts, ferns, and duckweed. Searchable via the MSDN.	http://www.butbn.cas.cz/ccala/ccala.htm
Algae, protozoa, and cyanobacteria—national center	United States	CCMP, Provasoli-Guillard National Center for Culture of Marine Phytoplankton Boothbay Harbor, Maine	Originated with the collections of Dr. Luigi Provasoli at Yale University and Dr. R. Guillard at Woods Hole Oceanographic Institution and became a national center as a result of recommendations of a 1980 workshop. Originally located at Woods Hole, but moved to the Bigelow Laboratory at Boothbay Harbor in 1981. Approximately 1450 cultures of primarily well-identified organism in pure culture. Special services include culture purification, safe deposit of private cultures, supplying mass cultures, DNA extractions, and occasional courses on culturing phytoplankton. Supported by the National Science Foundation. The culture database contains taxonomic and collection information, and the Website also presents information on culture techniques.	http://ccmp.bigelow.org
Algae	Germany	SVCK, the Culture Collection of Conjugatophyceae	Began at the Free University in Berlin and in 1959 moved to Marburg. Established at the Institute of General Botany of the University of Hamburg in the 1960s. Approximately 500 strains, collected world-wide. Education, training, and research functions. The Website lists culture and collection information by family.	http://www.rrz.uni-hamburg.de/biologie/lb_online/d44_1/44_1.htm
Cyanobacteria	France	PCC, Pasteur Culture Collection of Cyanobacteria	Axenic cyanobacterial strains, one of the specialized collections of the Institut Pasteur in Paris and the Collection Nationale de Cultures de Microorganismes (CNCM) of France. See National collection section of table. Member of the WFCC and ECCO. Information includes accession number, brief description, history of isolation, cross-references with other collections with same species, medium for growth, properties, synonymous names for the species, and references. Keyword searches or specific, designated property searches are provided on their Web search pages.	http://www.pasteur.fr/Bio/PCC/General.htm , http://www.pasteur.fr/recherche/banques/PCC
Algae and cyanobacteria	Russia	IPPAS, the Culture Collection of Microalgae, Moscow	Institute of Plant Physiology, Russian Academy of Sciences. Established in 1958 and contains 600 cultures of cyanobacteria and algae. Patent depository for countries of the former USSR. Member of the ECCO. On-line searches can be conducted via the MSDN.	http://wdcm.nig.ac.jp/CCINFO/CCINFO.xml? 596
Algae	Canada	NEPCC, North East Pacific Culture Collection of Marine Microalgae at the University of British Columbia	Founded by F. J. R. Taylor in the late 1960s. Supported by the Department of Botany of the university. Focuses on species of the North Pacific, but includes algae from other areas, and has many dinoflagellates. The Website lists the algae in the collection by family and gives collection and culturing information.	http://beluga.ocgy.ubc.ca/projects/nepcc
Algae and cyanobacteria	Canada	UTCC, University of Toronto Culture	Maintains and distributes cultures of over 350 isolates of primarily freshwater algae and cyanobacteria. Established in 1987 from several collections at the University of Toronto, with support from the Ontario Ministry of Colleges and Universities and currently from the Canadian Natural Sciences and Engineering Council and the university Department of Botany. Services include safe deposit, custom isolation of algae, identification, training, and specialized media preparation.	http://www.botany.utoronto.ca/utcc/index.html
Algae	Japan	Marine Biotechnology Institute (MBI) of Japan		See http://seaweed.ucg.ie/cultures/CultureCollections.html

VIII. ORGANIZATIONS PROMOTING CULTURE COLLECTIONS

Organizations fostering stock center activity include the previously cited ECCO, European Culture Collections Organization, national federations such as

the US Federation of Culture Collections and the Japan Federation of Culture Collections (which sponsor annual meetings as well as international meetings), UNESCO's MIRCEN, and the WFCC, World Federation of Culture Collections. An International Congress for Culture Collections, sponsored by the international federations, is held every 4 years.

Developmental processes in bacteria

Yves V. Brun

Indiana University

GLOSSARY

chemotaxis Movement toward or away from a chemical.

hypha (pl. hyphae) A single filament of a mycelium.

mycelium A network of cellular filaments formed by branching during the growth phase of fungi and actinomycetes.

phosphorelay A signal-transduction pathway in which a phosphate group is passed along a series of proteins.

regulon A group of genes controlled by the same regulatory molecule.

septum A partition that separates a cell into two compartments.

sigma factor The subunit of the RNA polymerase holoenzyme that confers promoter specificity.

surfactant A substance that reduces the surface tension of a liquid.

TCA cycle The cyclic pathway by which the two-carbon acetyl groups of acetyl-CoA are oxidized to carbon dioxide and water.

vegetative growth Exponential growth that usually occurs by simple binary cell division and produces two identical progeny cells.

Bacterial Development generates specialized cell types that enhance the ability of bacteria to survive in their environment. In addition to changes in gene expression, developmental processes in bacteria involve changes in morphology and changes in function that play an important role in the life cycle of the organism. Eukaryotic organisms add sexual reproduction to the functions of development, but bacterial developmental processes are asexual.

Bacteria use two basic strategies to respond to changes in their environment. In the first and simplest strategy, they induce the expression of genes that enable them to deal with the environmental change. For example, starvation for inorganic phosphate, the preferred source of the essential element phosphorus, induces the Phosphate (Pho) regulon. The Pho regulon includes genes for the high-affinity phosphate-transport proteins that increase the ability of the bacterium to transport phosphate and genes that allow the bacterium to metabolize organic forms of phosphate. These responses are relatively simple in that they usually involve a two-component regulatory system that activates the transcription of a set of genes required for the response. At the other extreme of complexity are bacteria that undergo complex developmental transformations in response to stress or as part of their normal life cycle. These developmental responses involve not only changes in gene expression, but also changes in cellular morphology, metabolic chemistry, and association with cells of other species.

I. FUNCTION OF DEVELOPMENT

Bacterial development produces cells that have four basic types of functions. Representative examples of these functions are given in Table 25.1. The most common product of bacterial development is a resting cell with relatively low metabolic activity and a higher resistance to physical and chemical stress than

TABLE 25.1 Examples of prokaryotic development^a

the vegetative cell; the best-studied example is endospore formation in *Bacillus subtilis*. The second type of function of differentiated cells is dispersal. Dispersal can be propelled by flagella or can simply be aided by wind, water, or animals in the case of nonmotile cells; the dispersal swarmer cell of *Caulobacter crescentus* is the product of an asymmetric division that also produces a sessile stalked cell. The

production of cells whose physiology is complementary represents the third type of function of bacterial development; this is best exemplified by formation of heterocysts that are specialized for nitrogen fixation in the Cyanobacterium *Anabaena*. Finally, bacterial development can lead to the establishment of a symbiotic relationship, as in the case of nodulation of legume roots by *Rhizobium*. Examples of the various developmental functions are presented here. In order to give a flavor of the research in this field, one example (*Caulobacter*) is described in slightly more detail.

II. ENDOSPORE FORMATION IN *BACILLUS SUBTILIS*

Endospore formation has been found exclusively in gram-positive bacteria and is best understood in *Bacillus subtilis*. The primary signal for the initiation of sporulation is nutrient starvation. Cell density is also important for efficient sporulation, presumably to ensure that cells are sufficiently abundant. It may be that if starving cells are at a high density, it is better to sporulate rather than compete for nutrients. However, if cells are at a low density, the chances of finding additional nutrients is higher and sporulation less desirable. Before initiating sporulation, cells monitor many intracellular factors, such as DNA replication and the TCA cycle. The integration of the extracellular and intracellular signals is regulated through a multicomponent phosphorelay that controls the phosphorylation of the transcriptional regulator SpoOA. The initiation of sporulation by the formation of a polar septum instead of the vegetative midcell septum requires the accumulation of a sufficient concentration of SpoOA~P. The subsequent engulfment of the prespore by the mother cell compartmentalizes the prespore inside the mother cell (Fig. 25.1). The genome of the mother cell provides the components for constructing the spore exterior and the genome of the forespore provides the components for constructing the spore interior. The forespore ultimately becomes a metabolically quiescent and stress-resistant spore that can give rise to future progeny by germination when conditions improve. The mother cell is discarded by lysis after the completion of sporulation.

The regulation of events in the mother cell and the forespore is due to the presence of four different sigma factors, two in each compartment, which assures that each genome gives rise to a different set of products (Fig. 25.2). Activation of σ^F in the forespore depends on polar septation. σ^E is synthesized as an inactive precursor whose activation by proteolytic processing in the mother-cell compartment is

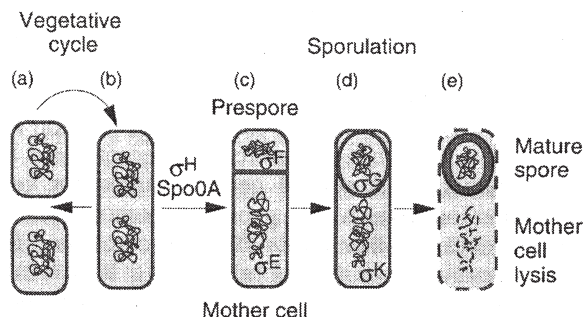

FIGURE 25.1 Life cycle of *Bacillus subtilis*. (a) Vegetative growth occurs by binary fission when nutrients are plentiful. (b) and (c) When starved, the vegetative midcell division is replaced by a highly asymmetric polar division that compartmentalizes the cell into a prespore and a mother-cell compartment. (d) The prespore is engulfed by the mother cell. (e) After formation of the spore cortex (thick circle), the mother cell lyses and releases the mature spore. [From J. Errington (1996). Determination of cell fate in *Bacillus subtilis*, *Trends in Genetics* 12: 31–34, Copyright (1996), with permission from Elsevier Science.]

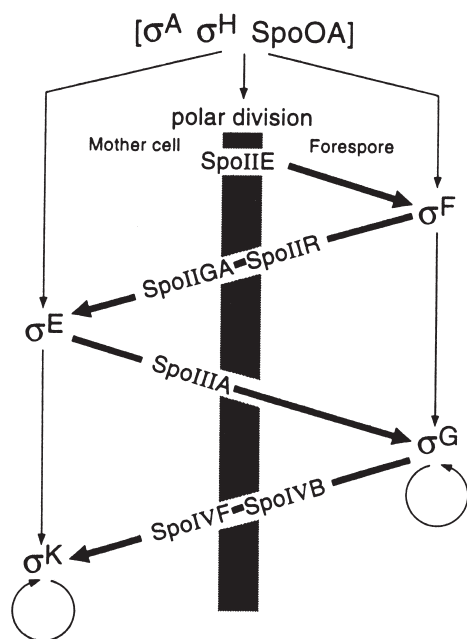

FIGURE 25.2 Criss-cross regulation of cell type-specific sigma factors. [With permission, from P. Stragier and R. Losick (1996). Molecular genetics of sporulation in *Bacillus subtilis*, *Annual Review of Genetics* 30: 297–341, © 1996 by Annual Reviews, www.annualreviews.org.]

dependent on activation of σ^F in the forespore. The transcription of the σ^G gene requires σ^F and thus only occurs in the forespore. σ^G activation depends on proteins made in the mother cell under the control of σ^E . Finally, σ^K is only synthesized in the mother cell under the control of σ^E and is activated in σ^G -dependent manner.

FIGURE 25.3 Scanning electron micrographs of spore chain in the aerial mycelium of *Streptomyces coelicolor*. Bar, 1 μm . [From K. Chater (1998). Taking a genetic scalpel to the *Streptomyces* colony. *Microbiology* 144: 1465–1478.]

III. SPORULATION IN *STREPTOMYCES COELICOLOR*

The aerial mycelium of *Streptomyces coelicolor* forms by directed cell growth and differentiates into a series of spores (Fig. 25.3). The vegetative mycelium grows in the nutrient substratum by the linear growth of cell wall close to the hyphal tip (Fig. 25.4). Branching of the vegetative mycelium allows close-to-exponential increase of the mycelial mass. Septation is infrequent in the vegetative mycelium and the vegetative septa do not allow cell separation. With time, the vegetative mycelium becomes more dense, producing aerial hyphae that grow quickly. Rapid growth occurs at the expense of nutrients derived from the substrate

FIGURE 25.4 Life cycle of *Streptomyces coelicolor*. Genes important in the different stages of the life cycle are shown. The phenotypes of various mutants are shown by arrows diverging from the normal life cycle immediately before the gene designation. [From K. Chater (1998). Taking a genetic scalpel to the *Streptomyces* colony. *Microbiology* 144: 1465–1478.]

mycelium and aerial hyphae emerge from the surface of colonies. The formation of the aerial hyphae requires a set of genes called *bld* genes because mutants of these genes fail to develop a hairy surface layer (*bald*). Most of these mutants fail to produce a small extracellular surfactant protein SapB. SapB coats the surface of the aerial hyphae with a hydrophobic outer surface. This may permit growth through the surface tension barrier at the air–colony interface. Antibiotics are produced, presumably to protect the nutrients released from lysing substrate mycelium from other bacteria. All antibiotic production, as well as aerial mycelium development, is prevented in *bldA* mutants. The *bldA* gene encodes the only tRNA that efficiently recognizes the rare leucine codon UUA. Genes required for vegetative growth do not contain TTA codons. TTA codons are found in regulatory genes involved in antibiotic production. It is thought that an increased production of mature *bldA*-encoded tRNA during development allows the efficient translation of UUA codons in regulators of antibiotic production and in genes involved in development whose identity is still unknown. Growth of the aerial hyphae eventually

stops and regularly spaced sporulation septa are formed synchronously. Thus, the cell separation required for dispersal occurs by sporulation at the surface of colonies. Sporulation requires *whi* genes, identified because mutations in these genes prevent the formation of mature grey spores and the aerial mycelium remains white. Most of the early-acting *whi* genes appear to be regulatory. *whiG* encodes a sigma factor, while *whiI* and *whiH* encode transcriptional regulators.

IV. SWARMING BACTERIA

Swarming differentiation produces cells (swarm cell) capable of a specialized form of translocation on a surface and occurs in a variety of bacteria, both gram-positive and gram-negative. These include *Proteus*, *Bacillus*, *Clostridium*, and *Vibrio* species, *Serratia marcescens*, *Rhodospirillum centenum*, *E. coli*, and *S. typhimurium*. The swarm cell differentiation is triggered by growth on an appropriate solid medium, for example a petri plate. Initially, cells grow vegetatively as short rods with a small number of flagella. Differentiated swarm cells are long (20–80 μm), multi-nucleate, non-dividing cells with up to 50-fold more flagella per unit cell-surface area than vegetative cells. Swarm cells migrate rapidly across the plate (Fig. 25.5). Swarming differentiation is not a starvation response and is not an obligatory stage in the life cycle of these bacteria. An important signal for swarm cell differentiation is bacterial contact with a solid surface. In *P. mirabilis* and *V. parahaemolyticus*, surface-sensing is mediated by the flagella. After a certain period, the migration of swarm cells slows down and the swarm cells divide (consolidation) and revert to the vegetative-swimmer cell type (Fig. 25.6). Vegetative growth continues until a second phase of swarm cell differentiation is initiated. This differentiation–consolidation cycle continues until the surface of the plate is covered. Swarming can have a function in host–pathogen interactions. For example, *Proteus mirabilis* mutants that are deficient in swarming are unable to establish kidney infections.

The *flhDC* master regulatory operon is critical for the control of swarming differentiation. Artificial overexpression of FlhDC induces swarm cell differentiation without the need for contact with a solid surface. FlhD and FlhC form a complex that activates transcription of genes encoding flagellar export, structural, and regulatory proteins. In addition, FlhDC represses cell division.

FIGURE 25.5 Swarming in *Proteus mirabilis*. (A) Electron micrograph of a swarmer cell. (B) Movement of a mass of cells at the swarming periphery. (C) Characteristic colony morphology. The pattern is produced by alternating cycles of differentiation, movement, and consolidation. [From BACTERIA AS MULTICELLULAR ORGANISMS, edited by James A. Shapiro and M. Dworkin. V. DIMORPHIC LIFE CYCLE OF CAULOBACTER CRESCENTUS

A distinguishing feature of the development of stalked bacteria is that it is an integral part of the growth of the cell and not an alternative to it, as are the other bacterial developmental processes that occur in response to stress. The molecular mechanisms that control the developmental cycle of stalked bacteria have been studied most extensively in *Caulobacter crescentus*. Each division of *Caulobacter* cells gives rise to a swarmer cell and a stalked cell (Fig. 25.7). The swarmer cell is dedicated to dispersal and the stalked cell is dedicated to growth and the production of new swarmer cells. The obligatory time spent as a chemotactic swarmer cell presumably ensures that progeny cells will colonize a new environmental niche instead of competing with attached stalked cells. The swarmer cell has a single polar flagellum and is chemotactically competent. During this dispersal stage of their life cycle, swarmer cells do not replicate DNA and do not divide. After approximately one-third of the cell cycle, in response to an unknown internal signal, the swarmer cell sheds its flagellum, initiates DNA replication, and synthesizes a stalk at the pole that previously contained the flagellum. Located at the tip of the stalk is the holdfast, the adhesion organelle that allows *Caulobacter* to attach to surfaces. The holdfast appears at the tip of nascent stalks during swarmer to stalked cell differentiation. Cell growth is accelerated at the time of swarmer-to-stalked cell differentiation and

FIGURE 25.7 The *Caulobacter crescentus* cell cycle. [From cover of *Genes and Development*, Vol. 12, No. 6. Kelly, A. J., Sackett, M., Din, N., Quardokus, E., and Brun, Y. V. (1998). Cell cycle dependent transcriptional and proteolytic regulation of FtsZ in *Caulobacter* *Genes and Development* 12: 880–893.]

eventually leads to the formation of a predivisional cell in which a flagellum is synthesized *de novo* at the pole opposite the stalk. Unlike the swarmer cell, the progeny stalked cell is capable of initiating a new round of DNA replication immediately after cell division.

A. Cell-cycle regulation of flagellum synthesis

The best understood event in *Caulobacter* development is the biosynthesis of the flagellum (Fig. 25.8). A new flagellum is synthesized at every cell cycle and is localized at the pole opposite the stalk. The flagellum is, for the most part, similar to that of *E. coli* and its synthesis requires more than 50 genes. The expression of these flagellar genes is temporally ordered during the progression through the cell cycle; their order of transcription approximates the order of assembly of their protein products in the flagellum. Most flagellar genes can be grouped into four classes, forming a regulatory hierarchy that dictates their order of expression. First to be transcribed, immediately after the differentiation of the swarmer cell into a stalked cell, are the gene for the MS ring that anchors the flagellar basal body in the cytoplasmic membrane, genes that encode the proteins of the switch complex, and genes for the flagellar export apparatus. In addition, Class II genes encode the regulatory proteins FlbD and σ^{54} that are required for the transcription of most Class III and IV genes. These early-expressed genes make up Class II in the flagellar regulatory hierarchy. The expression of Class II genes is required for the transcription of the next set of flagellar genes, the Class III genes. Class III genes encode proteins that make up the rest of the basal body (the rings anchored in the peptidoglycan cell wall and in the outer membrane and the rod that traverses the rings) and the proteins that compose the hook structure. The expression of Class III genes is required for the transcription of the last flagellar genes to be expressed during the cell cycle, the Class IV genes that encode the flagellins that make up the helical filament. The flagellar regulatory cascade is triggered by the response regulator CtrA, which by definition occupies Class I of the regulatory hierarchy. CtrA activates the transcription of Class II genes by binding to a conserved sequence in their promoter region. *In vitro* experiments indicate that phosphorylated CtrA (CtrA~P) is required for the transcriptional activation of these genes. The *flbD* gene is the last gene of the Class II *fliF* operon whose transcription depends on CtrA~P. The promoter of the *rpoN* gene contains a putative CtrA binding site. Consequently, the initiation of the

FIGURE 25.8 Cell cycle-dependent expression of *Caulobacter* flagellar proteins. (A) The expression of a representative protein from each class is shown. (B) Diagram of the *Caulobacter* flagellum. [From U. Jenal and L. Shapiro (1996). Cell cycle-controlled proteolysis of a flagellar motor protein that is asymmetrically distributed in the *Caulobacter* predivisional cell. *The EMBO Journal* 15: 2393–2406, by permission of Oxford University Press.]

transcription of Class II genes of the flagellar regulatory cascade by CtrA~P results in the synthesis of the regulatory proteins FlbD and σ^{54} , which are required for the transcription of Class III and IV genes. CtrA also regulates DNA replication and cell division, providing a mechanism to coordinate the expression of flagellar genes with those events (see next section).

B. Regulation of cell division and DNA replication

In *Caulobacter*, different stages of development require the completion of specific stages of the replication and division cycles. The inhibition of DNA replication blocks flagellum synthesis by preventing the transcription of early flagellar genes that are at the top of the flagellar regulatory hierarchy. Cells inhibited for DNA replication are also blocked for cell division and form long smooth filamentous cells with a stalk at one pole and flagella at the opposite pole. Cells that can replicate DNA, but that are blocked in cell division, are also affected in their progression through development. The initiation of cell division plays an essential role in the establishment of differential programs of gene expression that set up the fates of the progeny cells.

In all bacteria examined, the abundance and sub-cellular location of the tubulin-like GTPase, FtsZ, are critical factors in the initiation of cell division. FtsZ is a highly conserved protein that polymerizes into a ring structure associated with the cytoplasmic membrane at the site of cell division. FtsZ recruits other cell-division proteins to the site of cell division and may constrict, providing mechanical force for division. In *Caulobacter*, FtsZ is subject to a tight developmental control. After cell division, only the stalked cell contains FtsZ. Transcriptional and proteolytic controls contribute to the cell cycle and developmental regulation of FtsZ (see Fig. 25.9).

The initiation of DNA replication and *ftsZ* transcription are controlled by the cell-cycle-response regulator CtrA. CtrA directly binds to five sites in the origin of replication and prevents the initiation of DNA replication. CtrA is present in swarmer cells, where it blocks DNA replication and represses *ftsZ* transcription. CtrA is degraded during swarmer cell differentiation, thus coordinating the onset of the replication and division cycles. The degradation of CtrA depends on the ClpXP protease. Late in the cell cycle, when DNA replication is complete and cell division has been initiated, CtrA is synthesized and represses *ftsZ* transcription and initiation of DNA replication. Just before cell separation, CtrA is degraded in the

FIGURE 25.9 Model of FtsZ regulation in *Caulobacter*. CtrA (gray shading inside cells) represses *ftsZ* transcription in swarmer cells. During swarm cell differentiation, CtrA is degraded and allows *ftsZ* transcription to be turned on. FtsZ concentration increases and FtsZ polymerizes and forms a ring at the site of cell division. During this time FtsZ is stable. The reappearance of CtrA inhibits *ftsZ* transcription. FtsZ depolymerizes as the cell and the FtsZ ring constrict. FtsZ is rapidly degraded, especially in the swarmer pole. [From Kelly, A. J., Sackett, M. Din, N., Quardokus, E., and Brun, Y. V. (1998). Cell cycle dependent transcriptional and proteolytic regulation of FtsZ in *Caulobacter*. *Genes and Development* 12: 880–893.]

stalked compartment. The absence of CtrA from stalked cells after cell division allows *ftsZ* transcription to resume and DNA replication to be initiated.

Proteolytic control of FtsZ is superimposed on the transcriptional control. FtsZ molecules are stable as they assemble into the FtsZ ring and are degraded rapidly once cells have begun to constrict. FtsZ is particularly unstable in the swarmer compartment of the predivisional cell, leading to its disappearance from swarmer cells after cell division. This two-tiered level of regulation ensures that FtsZ is only present in the cell that will initiate a new cell cycle immediately after cell division.

VI. FRUITING-BODY FORMATION IN MYXOBACTERIA

Fruiting-body formation in myxobacteria is only one example of bacterial social behavior. The entire life cycle of myxobacteria is pervaded by social behavior. Myxobacterial cells move together and feed cooperatively to maximize the efficiency of extracellular degradation. The enclosure of myxospores in the fruiting body allows them to be dispersed together and ensures that a sufficiently large population of cells will be present after germination to facilitate social interactions. The best-studied example of fruit-

ing-body formation in myxobacteria is in *Myxococcus xanthus* (Fig. 25.10). When cells perceive a nutritional down shift, they enter the developmental pathway that leads to fruiting-body formation (Fig. 25.11). Fruiting-body formation can only occur if cells are on a solid surface, to allow gliding motility, and if the cell density is high. When these three conditions are met, cells move into aggregation centers and eventually form mounds containing approximately 10,000 cells. As many as 90% of cells lyse during aggregation. The surviving cells differentiate into resistant and metabolically quiescent myxospores during the last stages of fruiting-body formation. Fruiting-body development is regulated by a series of intercellular signals. Five categories of signals are involved: (1) the A signal is a mixture of amino acids and peptides that serves to monitor cell density; (2) the B signal acts early in development and its production depends on the Lon protease, but the nature of the signal has not been identified; (3) the C signal is associated with the cell surface and is the last of the five signals to act, controlling both aggregation and sporulation (the chemical nature of C signal is not known; all mutations that prevent C-signal formation map to the *csgA* gene and the CsgA protein itself could be the signal or it could produce the signal through an enzymatic activity); (4) the D signal requires the normal function of the *dsgA* gene that encodes the translation initiation factor 3 (IF3) but neither the manner by which *dsgA*

functions in the production of the signal nor the identity of the signal are known; and (5) the E signal is thought to consist of branched-chain fatty acids liberated by a phospholipase and passed between cells to function as short-range signals.

VII. HETEROCYST DIFFERENTIATION IN CYANOBACTERIA

The purpose of heterocyst formation in cyanobacteria such as *Anabaena* is the production of a cell specialized for nitrogen fixation in order to separate two incompatible processes. The oxygen generated by the photosynthetic activity of vegetative cells is sufficient to inactivate the nitrogenase that is required to convert atmospheric N_2 to ammonium. When nitrogen fixation is required, the detrimental effect of oxygen is circumvented by sequestering nitrogenase in the anaerobic environment of the heterocyst, in an otherwise aerobic filament of vegetative cells. In the presence of ammonium or nitrate, cyanobacteria grow as undifferentiated vegetative filaments. When these cells are starved for nitrogen, heterocyst formation is induced (Fig. 25.12). The heterocyst is a terminally differentiated cell, but the differentiating cell passes through a proheterocyst stage that

FIGURE 25.12 *Anabaena* sp. strain PCC-7120 filaments grown in nitrate medium (A) Filaments were subjected to nitrogen step-down for 18 hr (B), and 24 hr (C) to induce heterocysts. Developing proheterocysts are indicated on one filament with arrowheads in (B), and mature heterocysts are indicated with triangles in (C). The strain used in these figures contains a reporter plasmid that does not affect wild-type development of heterocysts. Scale bar, 10 μ m. Photo by Ho-Sung Yoon.

can go back to vegetative growth under appropriate conditions. Single heterocysts form at approximately every 10 cells in a filament. Heterocyst pattern formation is controlled in part by a diffusible signal encoded by the *PatS* gene. The PatS peptide is produced by proheterocysts and inhibits development of neighboring cells by creating a gradient of inhibitory signal.

VIII. THE PREDATORY LIFESTYLE OF *BDELLOVIBRIO*

The predation of gram-negative bacteria by *Bdellovibrio* includes a dimorphic life cycle (Fig. 25.13). During the obligatory intraperiplasmic growth phase, *Bdellovibrio* use their prey's cytoplasmic contents as their growth substrate. During the attack phase, they search for a new prey but do not grow. No DNA replication occurs during the attack phase; however, RNA and protein are synthesized. Thus, in addition to their dispersal function, the attack cells have the ability to attach to and enter bacterial prey. The function of the intraperiplasmic cells is to grow and to produce more attack phase cells. Attack cells are highly motile (100 $\mu\text{m/s}$) by virtue of a single polar flagellum. The attack phase continues until a suitable prey is encountered or until energy is exhausted. The attack phase has been described as a "race against starvation to find a susceptible prey". *Bdellovibrio* attack cells attach to prey cells and enter the prey 5–10 min after attachment. The flagellum is shed during the entry process. The prey cell is transformed into a bdelloplast by the action of a glycanase that solubilizes part of the peptidoglycan. The biochemical modification of the prey's peptidoglycan and

lipopolysaccharide make the prey inaccessible to other *Bdellovibrio* cells. The *Bdellovibrio* cell then begins the systematic degradation of host macromolecules, which is complete in about 60 min. DNA replication begins during the intraperiplasmic growth phase and occurs without cell division to produce a multinucleate filament whose size is determined by the size of the prey, ranging from 4 to 100 times the length of an attack-phase cell. The inhibition of cell division during intraperiplasmic growth while DNA replication is occurring presents an interesting contrast to the usual coupling of replication and division in many bacteria. Swarming bacteria like *Proteus vulgaris* also inhibit cell division during growth as part of swarm cell differentiation. As part of the growth phase, *Bdellovibrio* incorporates some of the outer-membrane proteins of the prey directly into its own membrane. Once growth becomes limited by the depletion of nutrients, elongation ceases and cell division is initiated simultaneously between the nucleoids. Flagella are synthesized *de novo* and the bdelloplast is lysed, releasing the attack-phase cells.

IX. CONCLUSION

The study of bacterial development has had a major impact on our understanding of the bacterial cell. In particular, it is now clear that bacterial cells, even those that do not differentiate, are not simply bags of enzymes. Bacterial cells are highly organized at the level of protein localization. The spatial constraints of differentiating cells are combined with temporal constraints that control the ordered progression through the developmental program. A major challenge will be to determine how temporal and spatial control are integrated during bacterial development.

Diversity, Microbial

Charles R. Lovell

University of South Carolina

GLOSSARY

division The largest phylogenetic grouping within a domain. This grouping can be considered analogous to the kingdom and includes one or more phyla.

domain The largest phylogenetically coherent grouping of organisms. The three domains of living organisms are the Bacteria, the Archaea, and the Eucarya.

monophyletic A group of organisms descending from a common ancestor having the significant traits that define the group.

species (bacterial or archaeal) The smallest functional unit of organismal diversity consisting of a lineage evolving separately from others and with its own specific ecological niche.

subdivision The largest phylogenetic grouping within a division. This grouping can be considered analogous to a phylum, and includes one or more orders.

The Microorganisms include all organism taxa containing a preponderance of species that are not readily visible to the naked eye. As a consequence of this anthropocentric definition, the microbiota have historically included numerous types of organisms differing from each other at the most fundamental levels of cellular organization and evolutionary history. We typically consider the major groups of microorganisms to be the bacteria, archaea, fungi, algae, protozoa, and viruses. This collection spans the breadth of organismal evolutionary history and ecological function, and represents the great majority of the major phylogenetic divisions of living organisms. Although these

microbial groups differ from each other in many important ways, they have in common enormous diversity and great importance in the biosphere.

I. THE SIGNIFICANCE OF MICROBIAL DIVERSITY

We are only beginning to appreciate the true extent of microbial diversity and have only recently developed methods suitable for its exploration. Interest in this area has been spurred by the crucial roles microorganisms play in global ecology and in numerous human endeavors. Major ecological roles of microorganisms and applications of microbial products and processes in human enterprises are still being uncovered, but what we currently know provides an imposing picture of the importance of the microbiota in global and human ecology.

Microorganisms are prime movers in all ecosystems. They mobilize some elements by converting them from nonvolatile to volatile forms, permitting large-scale mass transport of these elements among different geographic locations. They capture carbon dioxide (and other one-carbon compounds) through several known fixation pathways, accounting for approximately 50% of global primary productivity. Microorganisms participate in and frequently dominate the interconversions of chemical compounds, producing and regulating the great variety of materials necessary to the biosphere. Effectively all decomposition processes, including spoilage of foods, are dominated by the microbiota. Microorganisms are found in

all environments in which liquid water and an energy source can be found. These include such extreme environments as polar sea ice (in fluid-filled channels and pockets), hydrothermal vents, hot and cold deserts, brines approaching salt saturation, extremely acidic and alkaline waters, and deep (> 1 km) subsurface solid rock formations. It can be accurately stated that the Earth is a microbial world.

Microorganisms also participate in a plethora of symbiotic (literally "living together") interactions with each other and with higher organisms. Some are common commensals using the products of their hosts without causing any discernible harm. Some form mutualistic interactions in which they and their hosts both actively benefit from the symbiosis. These mutualisms range from production of essential vitamins and facilitation of digestive processes by the microflora found in the digestive tracts of animals to the elegant and species- or strain-specific nitrogen-fixing interactions that occur between many plant species and bacteria. Finally, microorganisms are infamous for their parasitic interactions with higher organisms. These range from subtle, such as the influence of *Wolbachia* infections on sex determination in arthropods, to catastrophic. The impacts of pathogenic microorganisms on human populations have on occasion been devastating and the plagues that ravaged Europe and Asia throughout the Middle Ages are no more notable in this regard than the AIDS pandemic of the present. The impacts of parasites on the structuring of higher organism communities can obviously be very significant and, as Dutch elm disease demonstrates, even a single pathogen can drive a host species to local extinction.

The exploitation of microorganisms having useful properties is central to many human enterprises and has fostered substantial bioprospecting efforts. Numerous microbial products ranging from antibiotics to foods are important commodities, but perhaps the most significant impact of beneficial microorganisms lies in agriculture. Many microorganisms that grow in mutualistic interactions with plants have been used to increase crop yields and to control pests. Nitrogen-fixing mutualisms between plants and bacteria form the basis for crop rotation and can facilitate reclamation of overexploited or marginal lands. The mycorrhizal fungi, which grow in intimate association with plant roots, enhance the ability of plants to take up mineral nutrients and water. This type of symbiosis permits plant growth in many marginal environments and most plants participate in it. Numerous bacteria and non-mycorrhizal fungi colonize the surfaces of plants and can successfully outcompete potentially pathogenic organisms,

preventing infections. In addition, the highly specific insecticidal toxins produced by *Bacillus thuringiensis* have been harnessed in insect pest control strategies and offer the major advantage of not harming beneficial insect species. Agriculture is, and always has been, highly dependent on microorganisms.

The vast array of microbial activities and their importance to the biosphere and to human economies provide strong rationales for examining their diversity. Loss of biodiversity is an ongoing global crisis and loss of the microbiota indigenous to human-impacted environments or associated with higher organisms facing extinction is a very real concern. As a consequence of the growing recognition of the importance of species loss, achieving a meaningful assessment of microbial diversity has been the topic of several major workshops and meetings. This is a period of very active inquiry into microbial diversity.

A. Approaches to the examination of microbial diversity

Past studies of microbial diversity were highly dependent on our ability to isolate these organisms into pure (i.e. single species) laboratory cultures for characterization. However, in most environments only 1–5% of the microscopically visible Bacteria and Archaea can be successfully cultivated, and obtaining pure cultures of many algae, protozoa, and fungi is problematic. In addition, detailed morphological, physiological, and behavioral characterization of any microorganism can be extremely time-consuming. As a consequence, many pure culture isolates have only been partially characterized. Recent applications of molecular biological tools, chiefly the polymerase chain reaction (PCR), DNA–DNA hybridization, DNA cloning and sequencing, and efficient analysis of DNA sequences, have provided a means to catalog microorganisms without the necessity for isolation and offer useful methods for streamlining the characterization of pure cultures.

Commonly used strategies for assessing microbial diversity employ PCR to amplify specific bacterial genes extracted from samples from the environment of interest. Nucleotide sequences of the genes encoding the small subunit ribosomal RNA (16S rRNA for Bacteria and Archaea and 18S rRNA for the Eucarya), when properly aligned, provide substantial information on the relatedness of unknown organisms to known species and support the construction of phylogenetic trees for microorganisms (Fig. 26.1). Other genes of interest for characterizing microbial diversity encode key enzymes involved in microbially mediated processes [i.e. functional group genes; *nifH*

FIGURE 26.1 The universal phylogenetic tree showing the three domains of living organisms—the Archaea, the Bacteria, and the Eucarya (reproduced with permission from Woese, 1994).

(nitrogenase iron protein) for nitrogen fixation, *amoA* (ammonium monooxygenase) for ammonium oxidation, *rbcL* (ribulose biphosphate carboxylase/oxygenase) for CO₂ fixation, etc.]. The amplified gene sequences can be resolved using various gel electrophoresis methods to provide a fingerprint of the microbial community present in the sample, or they can be cloned into an appropriate vector for propagation and nucleotide sequence analysis. The sequences of these genes are then available for phylogenetic analysis and species-specific domains within them can be used in DNA–DNA hybridization studies to quantify organisms of interest in environmental samples. Similar phylogenetic analyses of uncharacterized pure cultures allow the relatedness of these organisms to known species to be efficiently determined. Knowledge of the type of organism studied greatly facilitates selection of appropriate testing criteria for its complete identification. These technologies, although not perfect, have opened the door to the vast unknown world of microorganisms, clarifying the relationships of microorganism groups to each other and to higher organisms and facilitating the cataloging of species that have thus far resisted isolation and cultivation efforts. The picture that has emerged shows that of the three known domains of living organisms two, the Bacteria and the Archaea, consist entirely of microorganisms, and the third, the Eucarya, contains many major microbial taxonomic divisions. It is also clear from recent and ongoing studies that many new taxonomic lineages of microorganisms await discovery. The following sections summarize what is known, or at least widely

TABLE 26.1 Estimated numbers of described and undescribed species in the major groups of microorganisms according to recent surveys^a

Group	Estimated described species	Estimated undescribed species
Bacteria	5500	> 1,000,000
Archaea	260	?
Fungi	72,000	> 1,500,000
Algae	40,000	> 200,000
Protozoa	40,000	> 200,000
Viruses	6500	> 1,000,000

^aSee Bibliography for sources.

accepted, about the diversities of the major groups of microorganisms and indicate some interesting areas in which information is mostly lacking. It should be noted that most current estimates of the diversity of all major microbial groups (Table 26.1) are quite conservative and may be significant underestimates of the true numbers.

II. BACTERIAL DIVERSITY

The Bacteria constitute an extremely diverse domain of prokaryotic microorganisms. They have a very simple cellular architecture, lacking the membrane-bound organelles characteristic of eukaryotic cells. They reproduce asexually, typically by simple fission, and are genetically haploid. Bacteria acquire soluble nutrients by transport across the plasma membrane but are unable to engulf colloids or particles through

any endocytosis mechanisms. Virtually all known bacterial taxa have cell walls composed of an aminosugar polymer called peptidoglycan and this material is unique to this domain. Numerous distinctions can also be found between the Bacteria and other types of organisms in the details of their information processing machinery (i.e. DNA replication, RNA synthesis, and protein synthesis systems), chromosome structure, flagellar structure, and many physiological features.

Although unified by many features of cell structure and function and clearly forming a monophyletic domain, the Bacteria encompass enormous physiological diversity and can be found in almost every conceivable ecological niche. These organisms are found in extreme environments ranging from Antarctic sea ice to superheated marine hydrothermal vents, from extremely dilute aqueous systems to solutions approaching salt saturation, from highly acidic waters approaching a pH value of 0 to alkaline waters with pHs in excess of 12, and from the near vacuum of the upper atmosphere to the crushing pressures of the Challenger Deep. Bacteria can even be found in the highly radioactive environment of nuclear power plant reactor chambers. Although a few very hot environments appear to be dominated by the Archaea, the bacteria are ubiquitous inhabitants of all other environments and are important (and sometimes the only) participants in numerous ecological processes. Bacteria dominate mineral cycling and degradative processes in most environments, are important primary producers, and participate in all known types of symbiotic interactions, including parasitism on higher organisms, mutualistic interactions with other microorganisms and with higher organisms, and even active predation by some bacteria (such as *Bdellovibrio* species) on other bacterial species. The Bacteria dominate the biosphere like no other type of organism on Earth.

The bacterial domain encompasses an imposing diversity of physiological properties and ecological functions. The bacteria also clearly exemplify many of the major problems frequently encountered in assessing microbial diversity. Simply stated, nothing concerning the proper identification, classification, or phylogenetic analysis of bacteria is simple. Detailed observation of natural bacteria is complicated by their small size and their frequent growth on surfaces and in multispecies associations (biofilms, microcolonies, etc.). Even when they can be observed with a suitable degree of precision, bacteria display very few taxonomically useful morphological features. Most are simply spherical or rod shaped and a given species cannot be differentiated from organisms having

similar shapes, but quite different activities, on the basis of appearance. As a consequence, bacterial identification is highly dependent on laboratory cultivation of species of interest in order to perform detailed physiological testing. However, the overwhelming majority of bacteria in nature cannot be readily cultivated on artificial laboratory growth media. Whether this is due to some incapacity of some observable cells or to our failure to formulate suitable growth media is not known, but the consequences for systematic appraisal of bacterial diversity are extremely important.

The lack of information obtainable through microscopic observations and the difficulties encountered in isolating even numerically dominant species into pure culture make bacterial diversity studies highly dependent on molecular biological approaches. Through such methods it is possible to determine phylogenetic relatedness of unknown bacterial species, including those that resist cultivation, to known species. However, complete characterization of new bacterial species still requires extensive physiological characterization of laboratory cultures. In addition, since bacteria reproduce asexually, the exact definition of a species is not completely clear. The general trend has been that intensively studied taxa are highly speciose, whereas less studied taxa tend to have few and sometimes genetically heterogeneous species. Finally, the species is not always the finest phylogenetically or ecologically significant subdivision of the Bacteria. Many (all?) species contain numerous strains that can be differentiated only through detailed molecular, physiological, and/or immunological testing. Strains are particularly important to us when they differ in their interactions with higher organism hosts. For example, different strains of a given *Rhizobium* species are nitrogen-fixing mutualists of different leguminous plant hosts. Each bacterial species, whether it associates with higher organisms or not, appears to be a radiation of closely related strains which may differ significantly in the ecological niches they exploit and which contribute to even greater bacterial diversity. Deciding the level of detail desirable in diversity studies and evaluating the feasibility of obtaining a complete catalog of bacterial diversity in all but the most species-poor environments are ongoing concerns.

Currently, there are 36 monophyletic divisions of bacteria (Fig. 26.2). These range from the *Proteobacteria*, a division which includes a great many well-characterized species, to the *Acidobacterium* division, which has only three cultivated species, and the 13 "candidate" divisions (Hugenholtz *et al.*, 1998) which currently lack characterized species altogether. Several additional division-level lineages are only

FIGURE 26.2 Phylogenetic tree showing the 36 currently recognized divisions of the Bacteria. Wedges represent division level groups of two or more sequences. Divisions containing characterized species are shown in black, and those containing only environmental sequences are shown in outline (reproduced with permission from Hugenholtz *et al.*, 1998). Scale bar represents 0.10 base changes per nucleotide in the 16S rRNA gene sequences examined.

represented by unique environmental 16S rRNA sequences. The total number of bacterial divisions is unknown but almost certainly in excess of 40. In addition to their phylogenetic coherence, some divisions are also unified in ecophysiological function (the Cyanobacteria, the Green Sulfur Bacteria, etc.), but it is important to note that this is the exception rather than the rule. For example, the *Proteobacteria* division includes numerous different physiological types ranging from aerobic heterotrophs to strictly anaerobic photoautotrophs and obligate intracellular parasites. The degree of physiological diversity within many divisions is unknown and is particularly problematic for divisions having no characterized species.

The combination of molecular phylogenetic analysis and classical physiological characterization provides a powerful approach for identifying new bacterial species and placing them into a phylogenetically coherent framework, but bacterial diversity presents an imposing challenge at all levels. At present (April, 2002), there are only about 5500 validly published bacterial species representing 993 genera. A total of only about 11,400 bacterial 16S rRNA gene sequences are currently available. It is clear that only a small fraction of bacterial diversity has been cataloged, even for most well-studied environments. The vast majority of bacteria have not been cultivated and unknown 16S rRNA gene sequences are routinely recovered. In

addition, many ecosystems, particularly in the tropics, await detailed study. Even common and easily accessed environments, such as temperate terrestrial soils and freshwater sediments, have been the subjects of few systematic surveys. Currently, it seems unlikely that an accurate estimate of bacterial diversity can be presented or defended.

III. ARCHAEOAL DIVERSITY

The Archaea, like the Bacteria, are prokaryotic in terms of their cellular architecture. They reproduce asexually and depend on dissolved substances for carbon and energy. There, however, the similarity between the two domains ends. The Archaea are quite different from the Bacteria in the cell wall polymers they produce, their unusual lipids, resistance to broad spectrum antibiotics that inhibit most bacteria, and numerous details of their information processing machinery. The discovery by Carl Woese that the Archaea constitute a distinct monophyletic domain divergent from both the Bacteria and the Eucarya (Fig. 26.1) not only made sense of the disparate characteristics of these organisms but also it revolutionized our understanding of the evolution and diversity of life on Earth.

Most of the Archaea that have been validly described and published are extremophiles falling into four major categories. These include the high salt-requiring extreme halophiles, the anaerobic methane-producing methanogens, various types of Archaea that grow optimally at extremely high temperatures (thermophiles or hyperthermophiles), and the cell wall-less archaeon *Thermoplasma*. The United States National Center for Biological Information (NCBI) GenBank database in 2002 listed a total of only 73 genera and 257 described species of Archaea. Several hundred sequences from unknown Archaea are also available, but we cannot make predictions about the characteristics of these organisms. Some general features of the known archaeal groups are given below.

The extreme halophiles inhabit highly saline environments and generally require oxygen and at least 1.5M NaCl for growth. Virtually all these organisms can grow at saturating levels of salt. Although such highly saline environments are relatively rare, the extremely halophilic Archaea display a surprising diversity of cell morphologies, from rods and cocci to flattened disks, triangles, and rectangles. Given the unusual environment in which these organisms grow, the currently described nine genera may include most of the diversity of extreme halophiles.

The methanogens are restricted to anoxic habitats and all produce methane. Suitable habitats for methanogens are much more common than the high-salt environments required by the extreme halophiles and consequently the known diversity of methanogens is greater. There are seven major groups of methanogens containing at least 25 genera, including extremely halophilic methanogens, some methanogens that require highly alkaline growth conditions, and several thermophilic types. Major methanogenic habitats include soils ranging from pH neutral to acidic peat-rich soils, all types of freshwater sediments, both geothermally heated and unheated marine sediments, and the digestive tracts of higher animals, such as ruminants, and those of arthropods, including insects and crustaceans. Given this broad range of methanogenic environments, it is clear that the diversity of these organisms could greatly exceed the current rather sparse collection of species.

The hyperthermophilic Archaea include all non-methanogenic organisms that require temperatures in excess of 80°C for optimum growth. These Archaea are the most extremely thermophilic of all known organisms and several can grow at temperatures in excess of 100°C. Most hyperthermophiles are obligate anaerobes and most use reduced sulfur compounds (mineral sulfur or H₂S) in their metabolism. Ideal conditions for these organisms can be found in sulfur and sulfide-rich geothermally heated waters, such as those of hot springs and deep-sea hydrothermal vents. Although such habitats can have extremely low pH values, most hyperthermophiles have been recovered from neutral pH to mildly acidic locations. The widespread occurrence of geothermally heated waters, soils, and sediments, and the range of pH values and nutrient chemistries occurring within them, tends to support the idea of substantial diversity of hyperthermophilic Archaea. Certainly, the current catalog contains a broad range of organisms differing in physiology and growth requirements.

Thermoplasma, the cell wall-less thermophilic Archaeon, appears to be very restricted in its habitat range. All but one strain of this organism has been isolated from self-heating coal refuse piles. Although other, less transient habitats for this organism have been sought, only one strain of *Thermoplasma* has been recovered from geothermal environments. With such a limited distribution and narrow habitat range, this archaeal subdivision would be predicted to have very limited diversity.

Based on 16S rRNA gene sequence analysis, these diverse organisms can be readily grouped into two major divisions (kingdoms; Fig. 26.3). The *Euryarchaeota* include the halophilic and methanogenic Archaea

FIGURE 26.3 Phylogenetic tree for the Archaea showing the major groups of currently undescribed Archaea. Abbreviations represent cloned environmental 16S rRNA gene sequences (for published sources, see Fuhrman and Davis, 1997). The following clones were obtained from water samples: NH clones, pN1 clones, p712 clones, and 4B7 from the Pacific Ocean; WHAR clones from Woods Hole, MA; SBAR from Santa Barbara, CA; OAR from Oregon; and ANT clones from Antarctica. pGrfA4 is from freshwater lake sediment and PVA clones are from a volcanic seamount near Hawaii. JM clones are from an abyssal holothurian and *Cenarchaeum symbiosum* is from an uncharacterized marine sponge symbiont. Scale bar represents 0.10 base changes per nucleotide in the 16S rRNA gene sequences examined (adapted with permission from Fuhrman and Davis, 1997).

growing at moderate temperatures and *Thermoplasma*. The *Crenarchaeota* include all the hyperthermophilic organisms. It is easy to see why most researchers have long considered Archaea to be confined to extreme environments and thus likely to be restricted to very limited diversity. However, new findings from moderate- to low-temperature environments show that unknown Archaea are prominent members of the

microbial communities found there. DNA extracted from samples of soils, marine and freshwater sediments, marine plankton, sponges, and the gut contents of holothurians (sea cucumbers) all contained 16S rRNA sequences specific to the Archaea. Archaea from these environments include a crenarchaeotal group that represents as much as 20% of the planktonic marine prokaryote assemblage (Fuhrman and

Davis, 1997) and appears to occur in both surface and deep marine waters worldwide. Sequences related to this marine group have also been recovered from freshwater sediments and terrestrial soils. Two newly recognized marine euryarchaeotal groups distantly related to *Thermoplasma* have also been discovered (Fuhrman and Davis, 1997). None of these organisms have been isolated into pure culture and little can be deduced about their physiologies and growth requirements. All that we currently know is that the Archaea are more diverse and far more abundant in nonextreme environments than was previously thought. It is worthwhile to consider that we have had the molecular biological tools required for discovery of these unknown Archaea for only a short time and that the Archaea have only been considered a separate domain for slightly longer than 20 years. We need to know a great deal more than we currently know in order to develop any meaningful estimates of archaeal diversity or any clear realization of their significance in most environments.

IV. FUNGAL DIVERSITY

The fungi are an extremely diverse division of the Eucarya that includes both unicellular species and species that grow as finely divided networks of filaments called hyphae. Unicellular species are all microscopic, but hyphal networks can support fruiting bodies that are readily visible without magnification. All are included among the microorganisms on the basis of their lack of differentiated tissues. Primary features that distinguish the fungi from other Eucarya are: (i) use of chitin as a cell wall polymer (but not in all fungi); and (ii) the absence of photopigments. Fungal nutritional requirements and core metabolic processes are neither unusual for eukaryotes nor particularly diverse. However, their morphologies and life cycles display considerable diversity, providing the basis for classical fungal taxonomy. This scheme has a serious limitation in that mature reproductive structures are required for correct identification of some organisms and these structures can be difficult to find or are produced haphazardly by some fungi. The operational solution to this problem has been inclusion of all fungi for which sexual reproductive structures have not been seen in a single polyphyletic subdivision. The seven classically defined fungal taxonomic subdivisions are given here.

The Ascomycota (Ascomycetes or sac fungi) include about 35,000 described species. Many species of the red, brown, and blue-green molds that cause food spoilage, as well as the powdery mildews that

cause Dutch elm disease and chestnut blight, are Ascomycetes. The Basidiomycota (Basidiomycetes or club fungi) include about 30,000 known species. Among these are the smuts, rusts, shelf fungi, stinkhorns, puffballs, toadstools, mushrooms, and bird's nest fungi. The human pathogen *Cryptococcus neoformans*, which causes cryptococcosis, is also a Basidiomycete, as are the important plant pathogens, the smuts and rusts. The Zygomycota (Zygomycetes) include about 600 known species. Among these are the common bread molds and a few species parasitic on plants and animals. The Deuteromycota (Deuteromycetes or fungi imperfecti) include all species for which a sexual reproductive phase has not been observed—about 30,000 known species. Several human pathogens, including the organisms causing ringworm, athlete's foot, and histoplasmosis, are included in this group. The aflatoxin-producing species *Aspergillus flavus* and *A. parasiticus*, important organisms in fungal food poisonings, are also in this group. Other Deuteromycetes are responsible for production of antibiotics or are used in production of foods, such as cheeses and soy sauce. When the reproductive (perfect) stage of a Deuteromycete is characterized, it is transferred from the fungi imperfecti to the appropriate group. These four subdivisions of fungi form a monophyletic cluster of true fungi. Molecular phylogenetic analysis has revealed that the remaining three classically defined fungal groups are more closely related to other types of organisms than to the four true fungal subdivisions. The Oomycota (Oomycetes or water molds) resemble fungi in that they grow in a finely branched network of hyphal filaments. However, the Oomycetes have cell walls composed of cellulose, produce motile asexual zoospores, and are closely related to the algal Phaeophyta and Chrysophyta. The Oomycetes are saprotrophs and several are important plant pathogens, the most famous of which is *Phytophthora infestans*, the organism responsible for the Irish potato famine. The Myxomycota (plasmodial slime molds; about 700 known species) and Acrasiomycota (cellular slime molds; about 50 known species) lack cell walls of any kind during vegetative growth, display amoeboid motility, and are related to the protozoa. Both types are saprotrophic and feed by phagocytosis. When food resources become limiting, both types of slime molds will form fruiting structures. None of the slime molds are known to be important plant or animal parasites or to produce commercially valuable products. However, slime molds are significant participants in organic matter turnover in soils.

The major ecological functions of fungi are well understood. Soil fungi are ubiquitous saprotrophs

and responsible for much of the decay of soil organic matter. These organisms are highly adapted to the saprotroph function, producing a variety of important extracellular enzymes for degradation of insoluble substrates and infiltrating the soil matrix and decaying organic matter through hyphal growth. Although primarily terrestrial, fungi are also found in aquatic ecosystems, including highly saline intertidal soils, and are particularly significant in the decay of plant materials in these environments. Fungi are also important members of the digestive tract flora of many animals and actively participate in the breakdown of plant materials, particularly in the ruminant animals and many insects.

Fungal growth at the expense of plant biomass is not confined to dead biomass. Some fungi are also very significant plant parasites responsible for economically important damage to crop plants. The complex relationship of the mycorrhizal fungi with their plant hosts, which can be characterized as mutualistic, parasitic, or fluctuating between these roles, should not be overlooked in this regard. The mycorrhizae promote plant growth in many cases and are very important agents in the structuring of plant communities, but they can also damage their hosts under stressful environmental conditions. Fungal parasitism in some cases results in spoilage of food products, particularly the seed heads of maturing grain crops. An interesting fungus important in the spoilage of grains is the Ascomycete *Claviceps purpurea*, which produces the alkaloid mycotoxin ergot. Ergot is a potent hallucinogen and consumption of ergot-contaminated rye is thought to have been the cause of medieval dancing fits, in which the populations of whole villages danced wildly until exhausted. Accusations of witchcraft and the resulting Salem witch trials and executions may also have been due to ergotism.

Although they are less frequently cited as inhabitants of extreme environments than the extremist species among the Bacteria or Archaea, the fungi can grow across a broad range of environmental conditions and include species that could certainly be considered extremophiles. In general, fungi can tolerate greater extremes of salinity, pH, and desiccation than non-extremophilic species of bacteria. The diverse array of fungi participating in the lichen symbiosis can be found from temperate to very cold and dry environments worldwide. The microbiota of the rock varnishes common in hot deserts and the endolithic microflora growing within rocks in the Antarctic dry valleys both include fungi. Fungi are found in anaerobic environments including subsurface marine sediments, water-saturated decaying organic matter, the

rumens of ruminant mammals, and the hindguts of numerous insect species. Fungi inhabit soils having temperatures from below freezing up to about 60°C. Any effort to catalog total fungal diversity should certainly include such extreme environments, which are clearly more common than is usually realized.

There are between 72,000 and 100,000 known species of fungi, but total species numbers have been estimated at approximately 1.5 million, approximately six times the estimated number of vascular plant species (Hawksworth and Rossmann, 1997). This estimate should certainly be considered conservative since it does not include the mostly undescribed fungi growing commensalistically, mutualistically, or parasitically in or on animals. The estimated millions of undescribed insect species in the tropics are particularly noteworthy in this regard. Since mutualistic and parasitic fungi are typically quite host specific, many of these insect species may harbor unknown fungi. Given the important ecological functions of fungi as saprotrophs in organic matter decomposition and symbionts of terrestrial plants, it is sensible to consider plants first in estimates of fungal diversity. However, the many interactions of fungi with animals are easily overlooked and a great many undescribed fungal species are likely to be involved in them. The tropics, with their abundance of plant and insect species that are found nowhere else, likely represent the largest global reservoir of undescribed fungi, and characterization of the diversity of tropical fungi has only started.

The introduction of molecular biological methods for phylogenetic characterization of fungi should greatly facilitate identification of unknown species, particularly those that do not reliably produce fruiting bodies. Classical description of new species on the basis of morphological and life cycle characteristics continues at a respectable rate, but most fungal species, including many already available in culture, herbarium, and private collections, have yet to be validly described. It is certain that discovery of new fungal species will be limited primarily by the resources available for this effort for many years to come.

V. ALGAL DIVERSITY

The algae are a diverse assemblage of photosynthetic Eucarya. Most species are unicellular and thus counted among microorganisms. Some are much larger and these macroalgae will not be discussed here. The algae all contain chlorophyll *a* as well as a variety of additional pigments, giving them

colorations ranging from green to yellow, red, and brown. All algae carry out oxygenic photosynthesis and most are essentially aquatic in character, including those found at the surface of saturated soils. The algae inhabit all moderate (i.e. non-extreme) marine and freshwater environments that receive sufficient light to support photosynthesis. They are also found in a variety of unusual or extreme environments, including Antarctic sea ice, mountain snow fields, hot springs (up to maximum temperatures of about 60°C), and acidic waters (pH 4 or 5). A few species are able to tolerate very dry environments, such as dry soils, and the endolithic algae grow within rocks in the extremely cold, dry environment of Antarctic dry valleys. The halophilic *Dunaliella* can be found in many salt lakes and is often the only oxygenic phototroph present. The algae are ubiquitous, although sometimes unnoticed, members of virtually all microbial communities wherever light is available.

Algal diversity is impressive. There are at least 40,000 known algal species, with an extrapolated total of more than 200,000 species. These organisms are not monophyletic and their classical taxonomy is largely based on morphology and a few key phenotypic traits. The most important of these is their performance of oxygenic photosynthesis, their panoply of photopigments, their cell wall structure and chemistry, and the carbon reserve materials they synthesize when light is not a limiting resource. Consideration of these traits lead to the division of the algae into six major groups; the Chlorophytes, the Euglenophytes, the Crysophytes, the Rhodophytes, the Phaeophytes, and the Pyrrophytes (Table 26.2). This phenotypic classification system, although internally consistent, does not reflect the evolutionary history or the true phylogeny of the algae. The cyanobacteria, once known as the Cyanophytes, are clearly bacteria and should not be included among the algae. The

Chlorophytes and Rhodophytes are closely related to the higher plants, but the Crysophytes and Phaeophytes are more closely related to the oomycetes, and the Pyrrophytes are more closely related to the ciliated protozoa.

The major ecological functions of the microalgae are reasonably well understood. Algae are important primary producers in most aquatic environments, including sediments exposed by tidal action, where they can contribute to the formation of elaborate and highly active microbial mats. The algae contribute an estimated 30–50% of global primary production and are perhaps most significant in offshore marine waters in which fixed carbon is in short supply. In coastal marine systems, a quite different role of algae is also observed. Many marine microalgae produce potent toxins. Toxin-producing dinoflagellates commonly belonging to the genera *Gymnodinium* and *Gonyaulax* can form massive blooms (red tides) resulting in severe losses to fisheries. Recently, the toxin-producing “ambush predator” dinoflagellate, *Pfiesteria piscicida*, was identified as an important pathogen responsible for fish kills along the Atlantic and Gulf coasts of North America. This organism has a very complex life cycle, including 24 distinct stages, and its toxin has potent activity against a variety of animals, including humans. Toxic algal blooms are increasing in frequency and have been linked to sewage and agricultural runoff into coastal marine waters and to transport of dinoflagellate cysts in ship ballast water. Such environmental impacts may acquaint us with other, once obscure taxa and reveal additional capacities in better known organisms.

The majority of algal diversity remains to be detected and described, and it is very likely that numerous new organisms will be recognized in the near future. This may be particularly true of bloom-producing species. However, the major algal phylogenetic lineages have

TABLE 26.2 Characteristics of the major groups of algae

Group	Common name	Morphology	Photopigments	Carbon reserves	Cell wall
Chlorophytes	Green algae	Unicellular or macroscopic	Chlorophyll <i>a</i> and <i>b</i>	Starch (α -1,4-glucan), sucrose	Cellulose
Euglenophytes	Euglenoids	Unicellular	Chlorophyll <i>a</i> and <i>b</i>	Paramylon (β -1,2-glucan)	None
Chysophytes	Golden-brown algae	Unicellular	Chlorophyll <i>a</i> , <i>c</i> , and <i>e</i>	Lipids	Silicate
Rhodophytes	Red algae	Unicellular or macroscopic	Chlorophyll <i>a</i> and <i>d</i> , phycocyanin, phycoerythrin	Floridean starch (α -1,4-glucan and α -1,6-glucan), fluoridoside (glycerol-galactoside)	Cellulose
Phaeophytes	Brown algae	Macroscopic	Chlorophyll <i>a</i> and <i>c</i> , xanthophylls	Laminarin (β -1,3-glucan), mannitol	Cellulose
Pyrrophytes	Dinoflagellates	Unicellular	Chlorophyll <i>a</i> and <i>c</i>	Starch (α -1,4-glucan)	Cellulose

probably been identified and important improvements in methods for analyzing photopigment profiles and algal morphologies should facilitate recognition of new microalgae in field samples. Much work remains, particularly in terms of detailed phylogenetic analyses, but it is fair to say that we understand the range of important algal niches in the environment and that the major ecotypes of algae have been identified.

VI. PROTOZOAL DIVERSITY

Like the algae, the protozoa are a diverse collection of eukaryotic microorganisms defined on the basis of a small set of phenotypic traits. The protozoa lack cell walls and pigmentation, and most are motile. The absence of photopigments separates these organisms taxonomically from the algae (Euglenophytes and Pyrrophytes are currently placed in the algae) and motility distinguishes them from the true fungi. The slime molds are motile, phylogenetically related to the protozoa, and probably should be counted among them. The protozoa are very widely distributed, inhabiting all aquatic environments in which temperatures are above freezing but below about 60°C as well as soils and the digestive tracts of many animals. The major ecological function of the protozoa is as primary consumers of other microorganisms, and they are important predators on bacteria, small microalgae, and each other. Protozoa can also take up high-molecular-weight organic solutes and colloids by means of pinocytosis and low-molecular-weight organic molecules by simple diffusion. Some protozoa grow primarily as saprotrophs, whereas others are important parasites of higher organisms. About 40,000 known species of protozoa have been documented, but this may be less than 25% of the total.

The major taxonomic groups of protozoa are the Mastigophora, the Sarcodina, the Ciliophora, and the Sporozoa. The Mastigophora are motile by means of flagella and are commonly known as flagellates. They are closely allied with the Euglenophytes, which are capable of purely heterotrophic growth and can lose their chloroplasts if maintained in the dark. Important flagellate parasites of higher organisms include the trypanosomes, such as *Trypanosoma gambiense*, the organism responsible for African sleeping sickness. The Sarcodina include the amoebas, which lack shells, and the foraminifera, which produce calcium carbonate shells during active growth. The Ciliophora are motile by means of cilia and feed primarily on particulate materials and microbial cells. Few ciliates are

parasitic on higher organisms. In contrast, the Sporozoa are all obligate parasites. This large group is characterized by the lack of motile adult stages and by absorption of organic solutes as their primary means of obtaining nutrition. The Sporozoa include the plasmodia, which are the pathogens responsible for malaria.

As is the case for the algae, the protozoa are not monophyletic. Phylogenetic analysis has revealed that the Ciliophora and Pyrrophytes are more closely related to each other than to the other protozoal or algal groups. Mastigophora and Euglenophytes are also more closely related to each other than to other groups. The Sporozoa are very diverse and include some lineages that are highly divergent from all other known eukaryotic lines of descent. Data from more protozoa, particularly among the Sporozoa, will be required to fully evaluate the several known phylogenetic lineages and to properly place newly discovered lineages. Such data will also be very helpful in eliminating synonymous species from the published literature.

Considerations of the ecological functions of the protozoa, as well as the absence of solid evidence for specific geographic distributions of protozoal species, imply fairly restricted species diversity for these organisms (Finlay *et al.*, 1998). The best studied large protozoal group in terms of diversity is the Ciliophora native to marine and freshwater sediments. Only about 3000 species are known, but based on the appearance of certain species in all suitable habitats these may represent the majority of extant species. In other environments even ciliate diversity is poorly characterized. Foissner (1997) estimated that 70–80% of soil ciliates are unknown and that global diversity of these organisms is in the range of 1300–2000 species. Ciliates in the digestive tracts of animals are also very poorly characterized and may represent a substantial pool of undocumented protozoal diversity. Certainly the gut flora of an animal species would be considered to reflect the habitat, population structure, food source(s), and digestive tract architecture of that animal and consequently be somewhat characteristic of that species. The diversity of all other groups of protozoa is much more poorly characterized than that of the ciliates, and estimates of 200,000 protozoal species may not be excessive.

Although the taxonomic characterization of protozoa remains difficult and time-consuming, molecular biological methods for phylogenetic analysis should greatly facilitate identification and description of new species. Given the ubiquity of some protozoal species across suitable habitats worldwide (Finlay *et al.*, 1998), characterization of protozoal diversity in certain

habitats may not be as difficult as currently thought. The largest underexplored reservoir of protozoal diversity appears to be animals, particularly arthropods, in which important protozoal digestive tract flora can be abundant and are poorly characterized. This presents a particular problem in the case of endangered animal species, whose flora may also be lost in the event of extinction.

VII. VIRAL DIVERSITY

No matter whether it is more correct to consider viruses as "living organisms" or as renegade genome fragments, the viruses have very important impacts on other types of organisms and should not be neglected in discussions of microbial diversity. These obligately parasitic entities have no independent physiological activities and require a suitable host for reproduction, which damages or destroys host cells. The importance and success of viruses as parasites in higher organisms is well known. Numerous illnesses in animals and plants have viral origins and the rapidity with which viruses spread through a susceptible host population can be alarming. The Influenza pandemic of 1918 was particularly noteworthy for its rapid propagation and lethality. Identification of such pathogenic viral strains and development of vaccines against them are foci of major national and international efforts.

In addition to the damage done by out-of-control viral reproduction, many viruses can affect their hosts more subtly through genetic modification. Temperate viruses can insert their genome into that of an appropriate host and be propagated as a stable provirus within the host for many generations. This interaction, called lysogeny in bacteria-virus systems, is a form of recombination and can confer new properties to the host. Important examples of this type of recombination-driven change in host phenotype are provided by the pathogenicity islands of *Vibrio cholerae*, enterohemorrhagic *Escherichia coli* strains, and some other enteric pathogens. These bacterial species and strains display pathogenic traits, such as adhesion to specific host receptors and toxin production, only if the correct provirus (prophage) is present. The genetic modifications brought about by lysogeny can not only dictate whether or not a host bacterium is pathogenic but also control the severity of infection by the recombinant pathogen. Many organisms, particularly microorganisms, harbor proviruses or provirus-like sequences in their genomes and the importance of most of these to the host organisms is unknown. Although we have been chiefly interested in viruses

that infect humans, our domesticated animals, and crop plants, all types of organisms have viral parasites. The impacts of these less studied viruses on their host populations in nature are only beginning to be unraveled. Recent findings indicate that viruses are active participants in microbial food web processes and may exert some control over microbial population dynamics in nature.

Perhaps the diversity of no other microbial group is as poorly characterized and as widely underestimated as that of the viruses. This is partly due to difficulties in identifying and cultivating the host organisms necessary for propagating the viruses found in the environment. Viral taxonomy, which was long dependent on phenotypic characteristics, such as host range, symptoms of infection, morphology of the viral particle, and the type of nucleic acid (single-stranded DNA or RNA or double-stranded DNA or RNA) composing the genome, now also employs nucleotide sequence analysis of viral genomes. However, most types of viruses remain to be identified and no hosts for these organisms are known. There are about 6500 described species of viruses, including 2500 animal viruses, 2000 plant viruses, and 2000 bacterial viruses. However, the total number of virus species has been estimated to be 500,000, and this may be a significant underestimate of true viral diversity.

Recent findings, particularly in aquatic systems, show that viruses are extremely numerous in nature (Paul *et al.*, 1996). Viral numbers are typically on the order of 10^9 – 10^{10} virions per litre of water and estimates of viral production in nature are very high. From 1 to 4% of bacteria in freshwater and marine systems contain mature viruses and, since complete viruses are only visible in cells during the final 10% of the viral replication cycle, actual frequencies of infected cells could be much higher. In addition, as many as 4% of bacteria in coastal marine waters may contain stable proviruses and much higher proportions of culturable aquatic species are known to be lysogenic. Viruses are present in all the microbial environments that have been examined to date and with numbers as high as those reported for aquatic systems, and because of the diversity of morphologies observed it is clear that viruses represent a vastly underestimated pool of microbial diversity. This is particularly apparent when we consider the fact that more than 70 different viruses, representing six major viral groups, have been isolated using a single marine bacterium as the host strain (Paul *et al.*, 1996). If this pattern holds true across all types of organisms, and there is no compelling reason to think that it may not, viral diversity is much greater than currently appreciated. In addition, many viruses are quite mutable,

adding genetic variation among related strains to the already large task of cataloging viral diversity. It is likely that each viral isolate represents only one of a radiation of closely related but distinguishable genotypes. This additional diversity within strains is not inconsequential, as is clear from the differences in pathogenicity among different variants of HIV and influenza A.

Although the occasional human pathogen, such as the Ebola virus, introduces itself through grim displays of lethality, most viruses will only be discovered and described through painstaking, systematic efforts. It is clear that this will require a major commitment of time and resources, but the foundations for describing natural viral diversity have been laid and this effort can be now undertaken with some expectation of long-term success. A key consideration is the types of microbial, plant, and animal hosts that should be emphasized in these studies although, as Ebola illustrates, the host range for a given virus may prove very elusive.

VIII. TOWARDS A FUNCTIONAL SURVEY OF MICROBIAL DIVERSITY

Currently, most of the earth's microbial diversity is completely unknown and current estimates of the numbers of species extant are widely considered to be significant underestimates. The microbiota likely dominate global biodiversity, and efforts to characterize microbial diversity and to determine the interplay between this diversity and ecosystem function have recently accelerated. Given the ever-expanding rate of global change brought about by human activities, two extremely important organizing foci for diversity assessment can be identified.

First, habitats that are currently threatened by human activities are clearly of immediate interest to diversity survey efforts. Most tropical regions of the world are either severely human impacted or threatened. This is of particular interest since these regions are home to an enormous diversity of plant and animal species. Each of these higher organism species is host to numerous commensal, mutualist, and parasitic microorganisms, and when a host organism faces extinction so too may some members of its microflora. Bioprospecting in the tropics for microorganisms that produce useful products has begun, but many novel species may be lost before they can be documented and preserved. Consideration of habitat loss and the potential for host organism extinction provide spatial

and temporal frames of reference for microbial diversity survey efforts.

Second, some microbial activities, such as nitrogen fixation, primary production, and methane oxidation, are clearly essential to proper ecosystem function and are restricted to specific functional groups of microorganisms. The diversity of a given functional group may be limited, as seems to be the case for methane-oxidizing bacteria and for nitrogen-fixing bacteria in some habitats. Low diversity may also be an important consideration for microorganisms that grow in symbiotic relationships with higher organisms in which the degree of specificity of the microorganisms for their hosts can be great. If the active species within an essential microbial functional group are lost due to habitat modification or local extinction of a higher organism host species, key local ecosystem functions could deteriorate. Evaluation of environmentally sensitive, low-diversity functional groups provides a rationale for exploring connections between microbial diversity and ecosystem function and an ecological focus for diversity survey efforts.

Clearly, much work will have to be done to support a meaningful assessment of microbial diversity. However, the technology necessary to pursue this effort exists, and some important work has already been done. Compiling this information and systematic elimination of synonymous listings will be greatly facilitated by use of the World Wide Web, and several relevant websites have already been constructed (Table 26.3). The future will certainly produce a much greater understanding of the extent and importance of microbial diversity and most likely even more questions.

DNA repair

Lawrence Grossman

The Johns Hopkins University

GLOSSARY

endonuclease Nuclease that hydrolyzes internal phosphodiester bonds.

excision Removal of damaged nucleotides from incised nucleic acids.

exonuclease Nuclease that hydrolyzes terminal phosphodiester bonds.

glycosylase Enzymes that hydrolyze N-glycosyl bonds linking purines and pyrimidines to carbohydrate components of nucleic acids.

incision Endonucleolytic break in damaged nucleic acids.

ligation Phosphodiester bond formation as the final stage in repair.

nuclease Enzyme that hydrolyzes in the internucleotide phosphodiester bonds in nucleic acids.

resynthesis Polymerization of nucleotides into excised regions of damaged nucleic acids.

transcription The synthesis of messenger and RNA from template DNA.

The Ability of Cells to survive hostile environments is due, in part, to surveillance systems which recognize damaged sites in DNA and are capable of either reversing the damage or of removing damaged bases or nucleotides, generating sites which lead to a cascade of events restoring DNA to its original structural and biological integrity.

Both endogenous and exogenous environmental agents can damage DNA. Many repair systems are regulated by the stressful effects of such damage, affecting the levels of responsible enzymes, or by modifying their specificity. Repair enzymes appear to be the most highly conserved

proteins showing their important role throughout evolution. The enzyme systems can directly reverse the damage to form the normal purine or pyrimidine bases or the modified bases can be removed together with surrounding bases through a succession of events involving nucleases, DNA-polymerizing enzymes, and polynucleotide ligases which assist in restoring the biological and genetic integrity to DNA.

I. DAMAGE

As a target for damage, DNA possesses a multitude of sites which differ in their receptiveness to modification. On a stereochemical level, nucleotides in the major groove are more receptive to modification than those in the minor groove, the termini of DNA chains expose reactive groups, and some atoms of a purine or pyrimidine are more susceptible than others. As a consequence, the structure of DNA represents a heterogeneous target in which certain nucleotide sequences also contribute to the susceptibility of DNA to genotoxic agents.

A. Endogenous damage

Even at physiological pH values and temperatures in the absence of extraneous agents, the primary structure of DNA undergoes alterations (Table 27.1). Many specific reactions directly influence the informational content as well as the integrity of DNA. Although the rate constants for many reactions are inherently low, it is because of the enormous size of DNA and its

TABLE 27.1 Hours needed for a single event at pH 7.4 at 37°C

Event	Single-stranded DNA (2×10^6 base pairs)	Double-stranded DNA (2×10^6 base pairs)	Molecular events per genome per day
Depurination	2.5	10	24×10^3
Depyrimidination	50.8	200	12×10^2
Deamination of C	2.8	700	3.4×10^2
Deamination of A	140.0	?	?

FIGURE 27.1 Deamination reactions have mutagenic consequences because the deaminated bases cause false recognition.

persistence in cellular life cycles that the accumulation of these changes can have significant long-term effects.

1. Deamination

The hydrolytic conversion of adenine to hypoxanthine, guanine to xanthine, and cytosine to uracil-containing nucleotides is of sufficient magnitude to affect the informational content of DNA (Fig. 27.1).

2. Depurination

The glycosylic bonds linking guanine in nucleotides are especially sensitive to hydrolysis—more than the adenine and pyrimidine glycosylic links. The result is that apurinic (or apyrimidinic sites) are recognized by surveillance systems and as a consequence are repaired.

3. Mismatched bases

During the course of DNA replication there are non-complementary nucleotides which are incorrectly incorporated into DNA and manage to escape the editing functions of the DNA polymerases. The proper strand and the mismatched base are recognized and repaired.

4. Metabolic damage

When thymine incorporation into DNA is limited either through restricted precursor UTP availability or through inhibition of the thymidylate synthetase system, dUTP is utilized as a substitute for thymidine triphosphate. The presence of uracil is identified as a damaged site and acted on by repair processes.

5. Oxygen damage

The production of oxygen, superoxide, or hydroxyl radicals as a metabolic consequence, as well as the oxidative reactions at inflammatory sites, causes sugar destruction, which eventually leads to strand breakage.

B. Exogenous damage

The concept of DNA repair in biological systems arose from studies by photobiologists and radiobiologists who studied the viability and mutagenicity in biological systems exposed to either ionizing or ultraviolet (UV) irradiation. Target theories, derived from the random statistical nature of photon bombardment, led to the identification of DNA as the primary target for the cytotoxicity and mutagenicity of ultraviolet light. In addition, most of the structural and regulatory genes controlling DNA repair in *Escherichia coli* were identified, facilitating the isolation and molecular characterization of the relevant enzymes and proteins.

1. Ionizing radiation

The primary cellular effect of ionizing radiation (Fig. 27.2) is the radiolysis of water which mainly generates hydroxyl radicals ($\text{HO}\cdot$). The hydroxyl radical is capable of abstracting protons from the C4' position of the deoxyribose moiety of DNA, thereby labilizing the phosphodiester bonds and generating single- and double-strand breaks. The pyrimidine bases are also subject to $\text{HO}\cdot$ addition reactions.

2. Alkylation damage

This modification occurs on purine ring nitrogens (cytotoxic adducts), at the O⁶ position on guanine, and

FIGURE 27.2 DNA backbone breakage by ionizing radiation.

DISTRIBUTION OF ALKYL PRODUCTS FROM

at the O4 positions of the pyrimidines (mutagenic lesions) and the oxygen residues of the phosphodiester bonds of the DNA backbone (biologically silent) (Fig. 27.3). Alkylating agents are environmentally pervasive, arising indirectly from many foodstuffs and from automobile exhaust in which internal combustion of atmospheric nitrogen results in the formation of nitrate and nitrites.

FIGURE 27.4 Bulky adducts formed in DNA exposed to benz(a)-pyrene.

3. Bulky adducts

Large, bulky polycyclic aromatic hydrocarbon modification occurs primarily on the N², N⁷, and C⁸ positions of guanine, invariably from the metabolic activation of these large hydrophobic uncharged macromolecules

to their epoxide analogs (Fig. 27.4). The major source of these substances is from the combustion of tobacco, petroleum products, and foodstuffs.

4. Ultraviolet irradiation

Most of the UV photoproducts are chemically stable; their recognition provided direct biochemical evidence for DNA repair. The major photoproducts are 5,6-cyclobutane dimers of neighboring pyrimidines (intrastrand dimers), 6,4-pyrimidine-pyrimidone dimers (6-4 adducts), and 5,6-water-addition products of cytosine (cytosine hydrates).

II. DIRECT REMOVAL MECHANISMS

The simplest repair mechanisms involve the direct photoreversal of pyrimidine dimers to their normal homologs and the removal of O-alkyl groups from the O⁶-methylguanine and from the phosphotriester backbone as a consequence of alkylation damage to DNA.

A. Photolyases (photoreversal)

The direct reversal of pyrimidine dimers to the monomeric pyrimidines is the simplest mechanism, and it is chronologically the first mechanism described for the repair of photochemically damaged DNA (Fig. 27.5). It is a unique mechanism characterized by a requirement for visible light as the sole source of energy for breaking two carbon-carbon bonds.

The enzyme protein has two associated light-absorbing molecules (chromophores) which can form an active light-dependent enzyme. One of the chromophores is FADH₂ and the other is either a pterin or a deazaflavin able to absorb the effective wavelengths of 365–400 nm required for photoreactivation

of pyrimidine dimers. It is suggested that photoreversal involves energy transfer from the pterin molecule to FADH₂ with electron transfer to the pyrimidine dimer resulting in nonsynchronous cleavage of the C⁵ and C⁶ cyclobutane bonds. Enzymes that carry out photoreactivation have been identified in both prokaryotes and eukaryotes.

B. Alkyl group removal (methyl transferases)

Bacterial cells pretreated with less than cytotoxic or genotoxic levels of alkylating agents before lethal or mutagenic doses are more resistant (Fig. 27.6). This is an adaptive phenomenon with anti-mutagenic and anti-cytotoxic significance. During this adaptive period, a 39-kDa Ada protein is synthesized that specifically removes a methyl group from a phosphotriester bond and from an O⁶-methyl group of guanine (or from O⁴-methyl thymine). The O⁶-methyl group of guanine is not liberated as free O⁶-methyl guanine during this process, but it is transferred directly from the alkylated DNA to this protein; the Ada protein (methyl transferase) and an unmodified guanine are simultaneously generated. These alkyl groups specifically methylate cysteine 69 and cysteine 321, respectively, in the protein.

The methyl transferase is used stoichiometrically in the process (does not turnover) and is permanently inactivated in the process. Nascent enzyme, however, is generated because the mono- or dimethylated transferase activates transcription of its own "regulon" which includes, in addition to the *ada* gene, the *alk* B gene of undefined activity and the *alk* A gene which sponsors a DNA glycosylase. The latter enzyme acts on 3-methyl adenine, 3-methyl guanine, O²-methyl cytosine, and O²-methyl thymine. The methylated Ada protein can specifically bind to the operator of the *ada* gene acting as a positive regulator. Down regulation may be controlled by proteases acting at two hinge sites in the Ada protein.

FIGURE 27.5 The direct photoreversal of pyrimidine dimers in the presence of visible light.

FIGURE 27.6 The direct reversal of alkylation damage removes such groups from the DNA backbone and the O⁶ position of guanine. Such alkyl groups are transferred directly to specific cysteine residues on the transferase, the levels of which are influenced adaptively by the levels of the alkylating agents. The methylation of the transferase inactivates the enzyme which is used up stoichiometrically in the reaction. The alkylated transferase acts as a positive transcriptional signal turning on the synthesis of unique mRNA. Regulation of transferase levels may be influenced by a unique protease.

III. BASE EXCISION REPAIR

A. Base excision repair by glycosylases and apyrimidinic or apurinic endonucleases

Bases modified by deamination can be repaired by a group of enzymes called DNA glycosylases, which specifically hydrolyze the N-glycosyl bond of that base and the deoxyribose of the DNA backbone generating an apyrimidinic or an apurinic site (AP site) (Fig. 27.7). These are small, highly specific enzymes that require no cofactor for functioning. They are the most highly conserved proteins, attesting to the evolutionary unity both structurally and mechanistically from bacteria to man. As a consequence of DNA glycosylase action, the AP sites generated in the DNA are acted on by a phosphodiesterase (Fig. 27.8) specific for such sites that can nick the DNA 5' and/or 3' to such damaged sites. If there is a sequential action of a 5' acting and a 3' acting AP endonuclease, the AP site is excised generating a gap in the DNA strand.

FIGURE 27.7 DNA glycosylases hydrolyze the N-glycosyl bond between damaged bases and deoxyribose generating an AP (apyrimidinic or apurinic) site (arrow).

FIGURE 27.8 Endonucleases recognize AP sites and hydrolyze the phosphodiester bonds 3', 5', or both sides of the deoxyribose moiety in damaged DNA.

B. Glycosylase-associated AP endonucleases

An enzyme from bacteria and phage-infected bacteria, encoded in the latter case by a single gene (*den*), hydrolyzes the N-glycosyl bond of the 5' thymine moiety of a pyrimidine dimer followed by hydrolysis of the phosphodiester bond between the two thymine residues of the dimer (Fig. 27.9). This enzyme, referred to as the pyrimidine dimer DNA glycosylase, is found in *Micrococcus luteus* and phage T4-infected *E. coli*. This small, uncomplicated enzyme does not require cofactors and is presumed to act by a series of linked β elimination reactions. An enzyme behaving in a similar glycosylase–endonuclease fashion but acting on the radiolysis product of thymine is thymine glycol, which has been isolated from *E. coli* and is referred to as endonuclease III.

FIGURE 27.9 The same enzyme that can hydrolyze the N-glycosyl residue of a damaged nucleotide also hydrolyzes the phosphodiester bond linking the AP site generated in the first N-glycosylase reaction.

IV. NUCLEOTIDE EXCISION REPAIR

The ideal repair system is one that is somewhat indiscriminate and which can respond to virtually any kind of damage. Such a repair system has been characterized in *E. coli* in which it consists of at least six gene products of the *uvr* system. This ensemble of proteins consists of the UvrA protein that binds as a dimer to DNA in the presence of ATP, followed by the UvrB protein which cannot bind DNA by itself. Translocation of the UvrA₂B complex from initial undamaged DNA sites to damaged sites is driven by a cryptic ATPase associated with UvrB which is activated by the formation of the UvrA₂B-undamaged DNA complex. This complex is now poised for endonucleolytic activity catalyzed by the interaction of the UvrA₂B-damaged DNA complex with UvrC to generate two nicks in the DNA seven nucleotides 5' to the damaged site and the three or four nucleotides 3' to the same site. These sites of breakage are invariant regardless of the nature of the damage. In the presence of the UvrD (helicase III), DNA polymerase I, and substrate deoxynucleoside triphosphates, the damaged fragment is released and this is accompanied by the turnover of the UvrA, UvrB, and UvrC proteins. The continuity of the DNA helix is maintained based on the sequence of the opposite strand. The final integrity of the interrupted strands is restored by the action of DNA polymerase I, which copies the other strand, and by polynucleotide ligase, which seals the gap (Fig. 27.10). The levels of the Uvr proteins are regulated in *E. coli* by an "SOS" regulon monitoring many genes, including *uvrA*, *uvrB*, possibly *uvrC*, and *uvrD*, as part of the excision repair system. It also includes the regulators of the SOS system, the *uvrD* and *recA* proteins; cell division genes *sulA* and *sulB*; recombination genes *recA*, *recN*, *recQ*, *uvrD*, and *ruv*; mutagenic by-pass mechanisms (*umuDC* and *recA*); damage-inducible genes; and the lysogenic phage λ . The LexA protein negatively regulates these genes as a repressor by binding to unique operator regions. When the DNA is damaged (e.g., by UV light), a signal in the form of a DNA repair intermediate induces the synthesis of the RecA protein. When induced, the RecA protein acts as a protease assisting the LexA protein to degrade itself, activating its own synthesis and that of the RecA protein as well as approximately 20 other genes. These genes permit the survival of the cell in the face of life-threatening environmental damages. Upon repair of the damaged DNA, the level of the signal subsides, reducing the level of RecA and thus stabilizing the integrity of the intact LexA protein and its repressive properties on all

FIGURE 27.10 Nucleotide excision reactions. In this multiprotein enzyme system the UvrABC proteins catalyze a dual-incision reaction seven nucleotides 5' and three or four nucleotides 3' to a damaged site. The UvrA protein, as a dimer, binds to undamaged sites initially and in the presence of UvrB, whose cryptic ATPase is manifested in the presence of UvrA providing the energy necessary for translocation to a damaged site. This pre-incision complex interacts with UvrC, leading to the dual-incision reaction. The incised DNA-UvrABC does not turnover and requires the coordinated participation of the UvrD and DNA polymerase reactions for damaged fragment release and turnover of the UvrABC proteins. Ligation, the final reaction, restores to integrity the DNA strands.

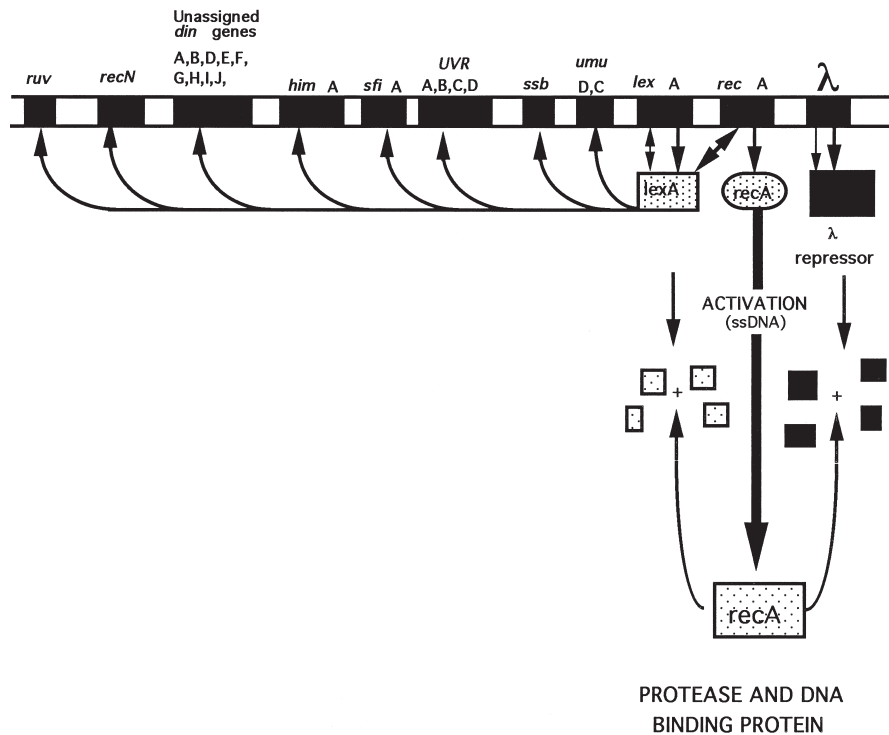

FIGURE 27.11 Regulation of the nucleotide excision pathway by the “SOS” system. The *lex A* and phage λ repressors negatively control a multitude of genes which are turned on when bacterial cells are damaged. This leads to the over-production of the *recA* protein which assists in the proteolysis of the *LexA* and phage λ proteins, thereby derepressing the controlled gene systems. When DNA is fully repaired the level of *recA* declines, restoring the “SOS” system to negative control.

the other genes (Fig. 27.11). Then the cell returns to its normal state.

V. TRANSCRIPTION-COUPLED NUCLEOTIDE EXCISION REPAIR

It appears that the structural and biological specificity associated with transcriptional processes limit DNA repair to those damaged regions of the chromosome undergoing transcription and that damage in those quiescent regions is persistent. Within expressed genes the repair process is selective for the transcribed DNA strand for damage such as pyrimidine dimers, and this "coupling" to transcription has been shown in *E. coli*. As a consequence, DNA repair occurs preferentially in active transcribed genes. Preferential repair occurs in the transcribed strand in actively expressed genes. Nucleotide excision repair (NER) differs in the two separate DNA strands of the lactose operon of UV-irradiated *E. coli*. The level of repair examined in the uninduced condition is about 50% after 20 min in both strands. As a consequence of a 436-fold induction of β -galactosidase, most of the dimers (70%) are removed from the transcribed strand of the induced operon within 5 min, whereas the extent of repair in nontranscribed strands is similar to that of the uninduced condition. This selective removal of pyrimidine dimers from the transcribed strand of a gene is abolished in the absence of significant levels of transcription.

As shown in Figs. 27.12 and 27.13, the RNAP when binding to its promoter site generates a defined distortion 3' (downstream) to the RNAP binding site which provides a "landing site" for the UvrA₂B complex. Strand specificity is dictated by the 5' → 3' directionality of the UvrA₂B helicase which can translocate only on the non-transcribed strand because RNAP interferes with the directionality on the lower strand. Nicking occurs only on the strand opposite to the strand which the UvrA₂B endonuclease binds; hence, it is the transcribed strand which is initially repaired in this model.

A. Effect of pyrimidine dimers on transcription and effect of RNAP on repair

T-T photodimers in the template strand constitute an absolute block for transcription, whereas those in the complementary strand have no effect. Irradiation of cells with UV results in truncated transcripts because the pyrimidine dimers become a "stop" site. In the absence of ribonucleoside triphosphates, promoter-bound RNAP does not translocate and, hence, has no effect on repair on a T-T photodimer downstream from the transcriptional initiation site no matter whether the photodimer is in the transcribed or in the nontranscribed strand.

B. Transcription repair coupling factor

Transcription repair coupling (TRC) is achieved through the action of the transcription repair coupling

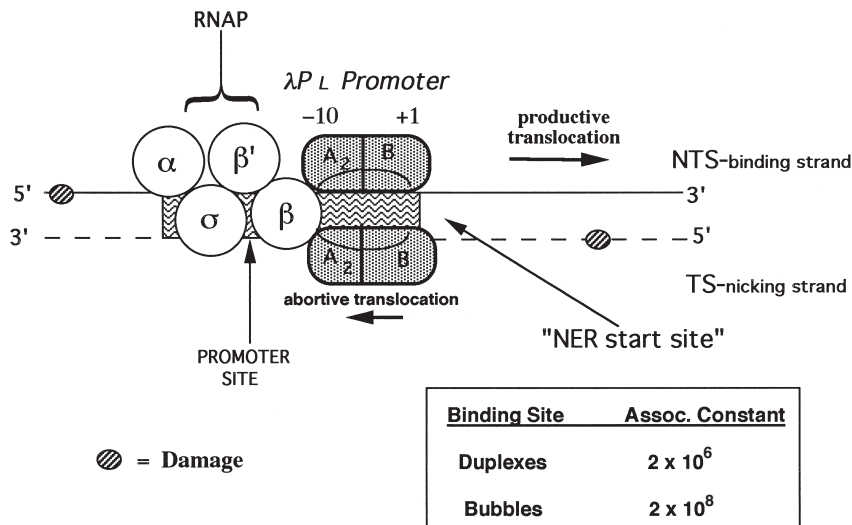

FIGURE 27.12 Strand selectivity by the *E. coli* UvrA₂B helicase.

FIGURE 27.13 Relief of RNAP-damaged sites as stalled complexes by the TRCF when RNA precedes the Uvr complex.

factor (TRCF). TRCF is the product of the *mfd* gene (*mutation frequency decline*), which maps at 25 min on the *E. coli* chromosome. The cloned *mfd* gene is translated into a 1148-amino acid protein of ~130 kDa. The Mfd protein can nonspecifically bind dsDNA (and less efficiently ssDNA) in an ATP-binding-dependent manner, with the ATP hydrolysis promoting its dissociation. The amino acid sequence of Mfd reveals motifs which are characteristic of many DNA and RNA helicases. However, *in vitro* purified Mfd does not show either DNA or RNA helicase activity. N-terminal 1–378 residues of Mfd, have a 140-amino acid region of homology with UvrB and bind UvrA protein.

In vitro transcription is inhibited by NER damage in a transcribed strand, whereas it has no effect on the noncoding strand. This inhibition is thought to result from a stalled RNAP at the site of damage. TRCF is able to release the stalled RNAP in an ATP hydrolysis-dependent manner. Moreover, it actually stimulates NER of the transcribed strand, so that it becomes faster than the nontranscribed one. Based on all these observations, it is concluded that TRCF-Mfd carries out preferential repair of the transcribed strand by (i) releasing RNAP stalled at damaged sites and (ii) recruiting the UvrA₂B complex

to damaged sites through the high-affinity interaction with UvrA.

VI. MISMATCH CORRECTION

Many mechanisms do not recognize damage but do recognize mispairing errors that occur in all biological systems (Fig. 27.14). In *E. coli* mismatch correction is controlled by seven mutator genes; *dam* (methyl directed), *mutD*, *mutH*, *mutL*, *mutS*, *mutU*, *worD*, and *mutY*. In mismatch correction one of the two strands of the mismatches is corrected to conform with the other strand. Strand selection is one of the intrinsic problems in mismatch repair and the selection is achieved in bacterial systems by adenine methylation, which occurs at d(GATC) sequences. Since such methylation occurs after DNA has replicated, only the template strand of the nascent duplex is methylated. In mismatch repair only the unmethylated strand is repaired, thus retaining the original nucleotide sequence. The MutH, MutL, and MutS proteins appear to be involved in the incision reaction on this strand, with the remainder of the proteins plus DNA polymerase III and polynucleotide ligase participating in the excision–resynthesis reactions.

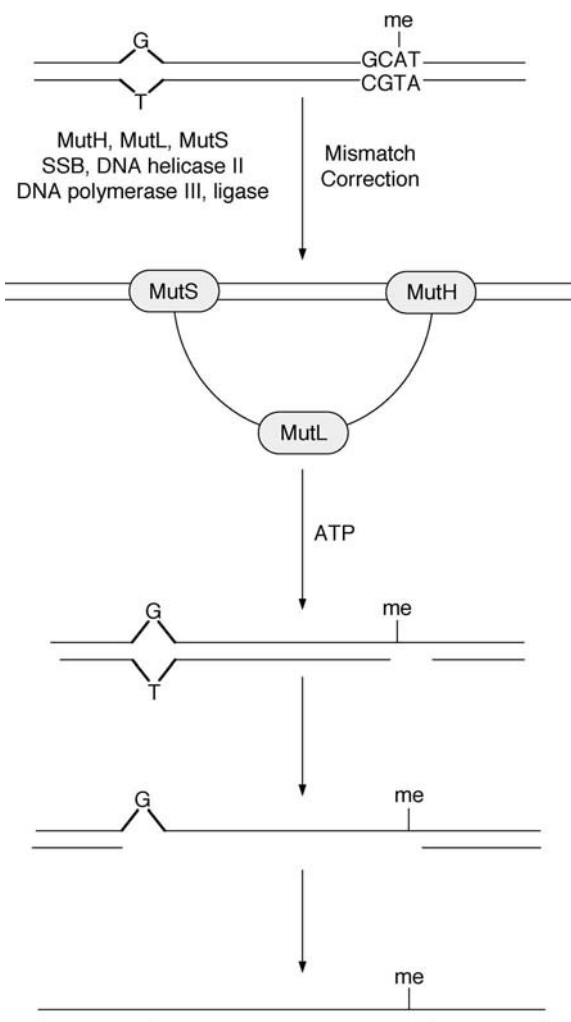

FIGURE 27.14 In the repair of mismatched bases strand distinction can be achieved by the delay in adenine methylation during replication. It is the nascent unmethylated strand which serves as a template for the incision reactions catalyzed by many proteins specifically engaged in mismatch repair processes.

DNA replication

James A. Hejna and Robb E. Moses

Oregon Health Sciences University

GLOSSARY

chromosome Package of genes representing part or all of the inherited information of the organism.

exonuclease Enzyme that degrades DNA from a terminus.

gyrase Enzyme that introduces supercoiling into the DNA duplex in an adenosine triphosphate-dependent reaction.

helicase Enzyme that unwinds duplex DNA and requires adenosine triphosphate.

polymerase Enzyme that synthesizes a nucleic acid polymer.

replication Act of duplicating the genome of a cell.

replicon Replicative unit, either part or the whole of the genome; in *Escherichia coli*, the entire genome is considered a replicon.

topoisomerase An enzyme that alters the topology of DNA, either one strand at a time (type I) or two strands at a time (type II). Gyrase and Topoisomerase IV are type II enzymes.

DNA Replication in *Escherichia coli* is a carefully regulated process involving multiple components representing more than 20 genes participating in duplication of the genome. The process is divided into distinct phases: initiation, elongation, and termination. The synthesis of a new chromosome involves an array of complex protein assemblies acting in sequential fashion in a carefully regulated and reiterated overall pattern. The scheme for DNA replication is under careful genetic control. The process is localized on the DNA structure by both DNA sequence and topology and requires specific protein–DNA

interactions. DNA replication in *E. coli* is bidirectional and symmetrical.

I. DEVELOPMENT OF THE FIELD

This article will focus primarily on *Escherichia coli* as a model organism, with the assumption that what is true for *E. coli* is generally true for other prokaryotes. In gram-positive bacteria such as *Bacillus subtilis*, this assumption has been largely substantiated. Sequencing of several prokaryotic genomes has revealed homology to many of the genes involved in *E. coli* DNA replication. The development of our understanding of DNA replication in prokaryotes depends on a combination of biochemical and genetic approaches. Using several selection techniques, many laboratories isolated *E. coli* mutants that were conditionally defective (usually temperature sensitive) in DNA replication. This method of identifying genes involved in DNA replication assumed that defects of such genes resulted in the death of the cell. When a large series of mutants was assembled, they fell clearly into two broad categories: those in which DNA replication ceased abruptly following a shift to restrictive conditions and those in which DNA replication ceased slowly. The former class is called fast stop and the latter slow stop. The first category represents cells containing mutations in gene products that are required for the elongation phase of DNA replication, and the latter category contains cells with defects

in gene products that are required for the initiation of new rounds of DNA replication.

The identification of temperature-sensitive, *dnats*, mutants was one requirement for understanding DNA replication. The second requirement was the development of systems that could be biochemically manipulated but that represented all or part of the authentic DNA replication process in *E. coli*. Several successive systems offered increasing advantages. Systems in which permeable cells allowed free access of small molecules to minimally disturbed chromosomes were the earliest. These systems allowed definition of the energy and cofactor requirements for the elongation phase of DNA replication. The limitation was that they did not permit access by macromolecules to the replication apparatus and therefore did not allow complementation of defects in proteins required for DNA replication. Also, such systems did not allow the initiation of new rounds of replication.

The development of lysate replication systems rested on the recognition that the failure to maintain the complex process of DNA replication in early studies was due to dilution of the components, resulting in disassembly of the replication structure and loss of functions required for DNA replication. The concentrated lysate systems depended on the bacterial chromosome, but it was quickly recognized that small bacterial phage chromosomes could be utilized as exogenous templates for DNA replication because they permitted the addition of proteins to allow complementation of defects in DNA replication. Lysates made from mutants defective in a specific step of DNA replication could be used to define the step at which the defect occurred and to identify the protein product complementing the defect. This allowed assignment of protein products to genes. Such systems, however, did not allow the study of initiation of new rounds of DNA synthesis on the host chromosome.

Two theoretical shortcomings of such systems are (i) that such systems might not define all the proteins required for DNA replication by the host and (ii) that such systems might require a protein for replication of the phage DNA not ordinarily required by the host chromosome. The following general point derived from these studies is worth remembering: Although *E. coli* contains numerous proteins that have overlapping or similar enzymatic function, the participation of a protein in the replication process is carefully regulated, reflecting a specific role. The DNA polymerases are the best example. Each of the three recognized DNA polymerases of *E. coli* (Table 28.1) has similar enzymatic capabilities, but ordinarily only DNA polymerase III catalyzes replication. This restriction of activity can be partially explained on the

TABLE 28.1 DNA polymerases of *E. coli*

basis of protein-protein interactions. The complete basis for the regulation is not understood, and the reasons for its being advantageous to the cell are not clear.

II. CONTROL OF DNA REPLICATION

Control of DNA replication relies on the regulation of new rounds of replication. In *E. coli*, there are two components of control: the DnaA protein and the structure of the origin of DNA replication (*oriC*). The region of the *E. coli* origin of DNA replication is at 85 min on the genetic map (based on a total of 100 min). On the sequenced *E. coli* genome, the origin is located between nucleotides 3923371 and 3923602. Thus, there is a fixed site on the *E. coli* genome that represents the appropriate place for the initiation of DNA replication. This DNA initiation is referred to as "macroinitiation" as opposed to repetitive initiation, which must occur multiple times during the "elongation" phase of DNA replication. The latter is referred to as "microinitiation." It seems that the requirements for macroinitiation at the *oriC* region include those needed for microinitiation plus additional requirements. There is a region of approximately 250 bp that must be present for DNA replication to initiate.

A. Macroinitiation

Several features regarding this region are notable. There are multiple binding sites for the DnaA protein (the DnaA boxes) (Fig. 28.1). This is a nine-nucleotide sequence that has been shown to bind the DnaA protein. There are also multiple promoter elements, suggesting the involvement of RNA polymerase in macroinitiation. Possible DNA gyrase binding sites are also present. Another notable feature is the presence of multiple Dam-methylase sites (GATC sequence).

The definition of the *oriC* region depends on cloning of this region into plasmids constructed so that replication of the plasmid depends on the function of the

FIGURE 28.1 Macroinitiation at *oriC* of *E. coli*. DnaA protein binds to DnaA boxes R1–R4. The DNA is probably wrapped around the DnaA proteins, and a higher order nucleoprotein complex involving as many as 30–40 DnaA polypeptides is generated with the assistance of DNA-binding proteins, such as IHF, HU, and FIS. The winding of DNA into this complex leads to the compensatory unwinding of an AT-rich region adjacent to the DnaA boxes. Single-stranded DNA is then coated by Ssb protein. DnaC recruits DnaB, the helicase which drives the DNA unwinding at the replication fork, to the junction between single-stranded DNA and double-stranded DNA. Primase then associates with DnaB and synthesizes the RNA primer. The RNA primer is subsequently extended by DNA polymerase III holoenzyme as the DnaB helicase unwinds the chromosome ahead of the polymerase.

oriC sequence. This has allowed development of an *in vitro* assay system for macroinitiation of DNA replication. The cloning of *oriC* confirmed that the specificity of macroinitiation in *E. coli* resides in the origin.

The primary protein actor in macroinitiation is the DnaA protein. This protein binds at multiple sites within the *oriC* structure as noted. In addition to binding at the DnaA box consensus sequence, the DnaA protein displays a DNA-dependent adenosine triphosphatase (ATPase) activity and appears to display cooperative binding properties. This suggests that the possible role in initiation is a change of conformation of DNA by DnaA protein interactions. The DnaA protein also binds in the promoter region of the DnaA gene, suggesting autoregulation, which is supported by genetic studies. It appears that the DnaA protein must act positively to initiate DNA replication in *E. coli*.

Both protein and RNA synthesis are required for macroinitiation to occur in *E. coli*. The macroinitiation phase may be further subdivided into stages. The earliest step involves the binding of the DnaA protein to the *oriC* structure. This results in a conformational change of the origin. This complex then binds the

DnaA to DnaB and DnaC proteins (which are also required for the elongation phase of DNA replication). DnaC plays a unique role in the delivery of the DnaB protein to the replication structure. The resulting complex appears to unwind the DNA strands since the DnaB protein functions as a helicase, an ATP-dependent unwinding activity. This allows the binding of single-strand binding (Ssb) protein, which allows priming such as that which occurs in the elongation of DNA replication. This stage is followed by the propagation of microinitiation and elongation phases of replication.

Thus, the proteins required for the macroinitiation of *E. coli* DNA replication appear to include DnaA and DnaC, which have specific roles, as well as DnaB, Ssb protein, gyrase, the DnaG primase protein, and the replicative apparatus of DNA polymerase III holoenzyme complex (see Section III.B). Studies also suggest a direct role for RNA polymerase in the macroinitiation of DNA replication.

The DnaA protein offers important support of the replicon hypothesis. Mutations in the DnaA protein demonstrate that all of the *E. coli* chromosome is under a unit control mechanism which defines it as a

single replicon. Integration of certain low-copy number plasmids into the chromosome suppresses the phenotype in DnaA mutants that were defective in macroinitiation. This “integrative suppression” shows a general control of macroinitiation and supports the replicon hypothesis.

B. Microinitiation

Microinitiation is the hallmark of the elongation phase of DNA replication. During this phase, repeated initiation occurs along the DNA. The microinitiation step appears to be analogous to the initiation step studied in the *in vitro* lysate systems using small circular phage genomes. In the prokaryotic cell, the requirements for microinitiation appear to mimic those of the phage systems G4 and ϕ X174, which do not display a requirement for the DnaA protein or the features of the *oriC* region.

Cell proteins required for microinitiation include the DnaB protein. The DnaB protein contains a nucleoside triphosphate activity that is stimulated by single-stranded DNA. It also displays DNA helicase activity. In addition, it appears to undergo protein–protein interactions with the DnaC protein. The DnaB mutants are notable for a rapid cessation of DNA synthesis at restrictive conditions. It appears that the DnaB protein is one of the “motors” that moves the replication complex along the DNA (or moves the DNA through the replication complex). The DnaB protein is typical of the proteins involved in DNA replication in that it may have more than one role.

The DnaG protein of *E. coli* is the primase. This protein is capable of synthesizing oligonucleotides utilizing nucleoside (or deoxynucleoside) triphosphates. It appears that physiologically its role is to synthesize RNA primers, which can be utilized by the DNA polymerase III holoenzyme complex to initiate DNA synthesis. As shown in Fig. 28.2, at least some portion of DNA replication in most organisms is discontinuous. That is, part of the DNA is synthesized in short pieces (termed Okazaki pieces). This is the result of the restriction for DNA synthesis in the 5' → 3' direction. Since the replication fork requires apparent growth of the nascent strands in both the 5' → 3' direction and the 3' → 5' direction, studies were initiated that searched for precursors or enzymes that would allow growth in the 3' → 5' direction. None were found. The hypothesis of discontinuous synthesis states that, on a microscopic scale, DNA is synthesized discontinuously in a 5' → 3' direction in small pieces to allow an overall growth in the 3' → 5' direction on one strand (the lagging strand). This hypothesis predicts the existence of a relatively uniform class

FIGURE 28.2 Model of the replication region. O, the origin; A, primed, elongating nascent strand; B, the point at which the replicative enzyme will release from the A strand and reinitiate a new discontinuous strand.

of small nascent DNA strands prior to joining, and it also predicts joining activity for such DNA strands. Both of these predictions are fulfilled.

It appears that in *E. coli* DNA is synthesized on one lagging strand in pieces of approximately 1000 nucleotides, which are then covalently linked via the action of DNA ligase following synthesis. Because none of the DNA polymerases in prokaryotes have been found to initiate synthesis *de novo*, this hypothesis leads to the prediction that RNA synthesis, which can be demonstrated to initiate *de novo*, forms primers that are utilized for DNA strand synthesis. Identification of the DnaG primase activity satisfies this prediction.

The polarity restriction of DNA synthesis by DNA polymerases permits one strand to be made continuously, as indicated in the model. It appears that relatively few initiations are made in this (leading) strand and, in fact, that macroinitiation may serve to prime the whole length of the strand.

Ssb protein has analogs throughout nature. In *E. coli*, this protein is relatively small (approximately 19 kDa) and functions as a tetramer. This protein is required for DNA replication. It appears to have several roles. In the single-strand phage systems *in vitro* it confers specificity on the origin of DNA replication and there is no reason to doubt that it performs a similar role in *E. coli*. It probably maintains DNA in a more open state under physiologic conditions during DNA replication in the cell. Evidence suggests that the Ssb protein may participate in a nucleosome like structure (a nucleoprotein complex that compacts the chromosome, analogous to eukaryotic chromatin), perhaps with *E. coli* HU protein. HU, like IHF and FIS, is a small DNA-binding protein that bends the double

helix, thereby facilitating the action of other DNA-binding proteins such as DnaA. It is possible that the coating of DNA strands by Ssb protein protects against nucleolytic degradation during replication. Lastly, Ssb protein appears to stimulate the rate of synthesis of DNA polymerases under particular conditions. Whether or not this is the case during DNA replication is not clear.

The 5' → 3' exonuclease of polymerase I is essential in *E. coli*, and such an enzymatic activity meets the requirement for the elimination of leftover RNA primers on the lagging strand. After the replication fork has moved on, leaving a 3' terminus of the newly synthesized Okazaki fragment adjacent to an RNA primer, polymerase I extends the 3' terminus of the nascent DNA strand while digesting the RNA primer in a process called "nick translation." DNA ligase is required for joining the Okazaki pieces made during discontinuous DNA synthesis. This enzyme is also required for DNA replication because mutants conditionally defective in ligase are also conditionally defective in DNA synthesis.

In addition to the previously mentioned proteins, proteins such as DNA gyrase and DNA topoisomerase I (ω protein) may play a critical role during the microinitiation phase of DNA replication.

Genes *priA*, *-B*, and *-C* (for primosome), *dnaT*, and their products play a role in the assembly of the primosome structure and are required for replication of at least some single-stranded phages and plasmids. However, the effect on the cell of a deficiency is modest.

III. DNA STRAND SYNTHESIS

The genetics of DNA strand synthesis are reflected in the DNA polymerase. *Escherichia coli* is known to contain at least three distinct and separate DNA polymerases, all possessing the following enzymatic activities: synthesis exclusively in the 5' → 3' direction, utilization of 5' deoxynucleoside triphosphates for substrates, the copying of single-stranded DNA template, incorporation of base analogs or ribonucleoside triphosphates at low efficiency under altered conditions (such as in the presence of manganese), a 3' editorial exonuclease that preferentially removes mismatched 3' termini, and a rate of synthesis that does not approach that of DNA replication in the cell (Table 28.1). Despite these similarities, distinct physical differences exist, and the cell uses exclusively DNA polymerase III for DNA replication. The synthesis subunit for DNA polymerase III, the α subunit, is encoded by the *polC* (*dnaE*) gene.

A. DNA polymerases

DNA polymerase I, encoded by the *polA* gene, appears to be an auxiliary protein for DNA replication. Cells lacking this enzyme demonstrate viability, although those lacking the notable 5' → 3' exonuclease activity of this enzyme are only partially viable unless grown in high salt. DNA polymerase I is very important for survival of the cell following many types of DNA damage, and in its absence the cell has persistent single-stranded breaks that promote DNA recombination. DNA polymerase I appears to be a particularly potent effector with DNA ligase in sealing single-stranded nicks, perhaps because of its ability to catalyze nick translation in which the 5' exonucleolytic removal of bases is coupled to the synthesis activity. Neither of the other DNA polymerases appear to possess this property.

DNA polymerase II is an enzyme without a defined role in the cell. It has been cloned and overproduced and has been found to bear a closer relationship to T4 DNA polymerase and human polymerase alpha than to either of the other two *E. coli* DNA polymerases. Nevertheless, it is capable of interacting with the subunits of the DNA polymerase III complex. Cells that completely lack the structural gene for DNA polymerase II (the *polB* gene) show normal viability and normal repair after DNA damage in many circumstances. Among suggested roles is synthesis to bypass DNA damage.

DNA polymerase III is the required replicase of *E. coli*. The fact that it plays a significant role in DNA replication is demonstrated because *dnaEts* mutants contain a temperature-sensitive DNA polymerase III. Despite having properties similar to those of DNA polymerase I and II, DNA polymerase III is specifically required for DNA replication. This is a reflection of its ability to interact with a set of subunits that confer particular properties on the complex. In the complex (termed the holoenzyme) DNA polymerase III takes on the properties of a high rate of synthesis and great processivity. Intuitively, processivity may be thought of as the ability of an enzyme catalyzing the synthesis of DNA to remain tracking on one template for a long period of time before disassociating and initiating synthesis on another template. Highly processive enzymes are capable of synthesizing thousands of nucleotides at a single stretch before releasing the template. DNA polymerase III appears to be uniquely processive among the *E. coli* DNA polymerases.

B. Holoenzyme DNA polymerase III

In addition to the α -synthesis subunit, there are at least nine constituents of the DNA polymerase III

holoenzyme complex (Table 28.2). Most of them have been shown to be the products of required genes as demonstrated by the fact that mutations in that gene produce conditional cessation of DNA replication (*dnaE*, *dnaQ*, *dnaN*, and *dnaX*) or that “knockout” mutants are inviable (*holA*, encoding the δ subunit, and *holB*, encoding the “d” subunit). A knockout mutation of *holE* did not impair cell viability, implying that the θ subunit is dispensable for normal growth. The γ protein and the τ protein appear to be products of the same *dnaX* gene. This is a case in which frame-shifting termination of protein synthesis plays a role in producing different proteins from the same gene. Mutants constructed with a frameshift in the *dnaX* gene that abolish production of γ but do not affect τ are viable; however, τ has been shown to be essential. The β subunit is the product of the *dnaN* gene. This

subunit appears to confer specificity for primer utilization upon the complex and to increase the processivity. The ϵ protein of the holoenzyme complex is known to provide a powerful 3' editorial exonuclease activity. This is manifest by the fact that in addition to lethal mutants in this gene (*mutD*), mutants that show increased error rates in DNA replication (mutators) can be isolated.

Physical studies as well as genetic studies indicate that the DNA polymerase III holoenzyme complex exists in a dimer form. The stoichiometry of the various subunits suggests that the dimer is not exactly symmetrical, but it does appear to be symmetrical for the α , β , and ϵ subunits. The holoenzyme comprises two dimerized β subunits (β_4), a dimeric core pol III', ($\alpha_2\epsilon_2\theta_2\tau_2$), and a single γ complex ($\gamma_2d_1d_1\chi_1\psi_1$) that appears to be involved in loading the β processivity

TABLE 28.2 Proteins involved in *E. coli* DNA replication

Protein	Subunit	Gene	Size	Function
DnaA		<i>dnaA</i>	58	Conformational change of DNA at <i>oriC</i> , macroinitiation
DnaB		<i>dnaB</i>	52	ATP-dependent DNA helicase, unwinding DNA at the replication fork
DnaC		<i>dnaC</i>	27	Recruitment of DnaB to <i>oriC</i> -DnaA complex
Gyrase	A	<i>gyrA</i>	96	GyrA ₅₂ -GyrB ² tetramer maintains the chromosome in a negatively supercoiled state, affecting global regulation of replication, and possibly local regulation of initiation at <i>oriC</i>
	B	<i>gyrB</i>	88	ATPase subunit of gyrase
Topoisomerase IV	A	<i>parC</i>	83	Decatenation of replicated chromosomes
	B	<i>parE</i>	70	Subunit of topo IV
Topoisomerase I		<i>topA</i>	110	Relaxes supercoils, affecting global regulation of replication
Ssb		<i>ssb</i>	19	Protects single-stranded DNA from nucleolytic degradation
DNA polymerase III	α	<i>dnaE</i>	129.9	DNA synthesis
	ϵ	<i>dnaQ</i>	27.5	3' \rightarrow 5' proofreading exonuclease
	θ	<i>holE</i>	8.6	Stimulates ϵ
	τ	<i>dnaX</i>	71.1	Coordinates both halves of pol III holoenzyme by linking DnaB with pol III, interacts with primase
	γ	<i>dnaX</i>	47.5	Subunit of γ complex, β clamp loading; binds ATP
	δ	<i>holA</i>	38.7	Subunit of γ complex, interacts with β
	δ'	<i>holB</i>	36.9	Subunit of γ complex, cofactor of γ ATPase
	χ	<i>holC</i>	16.6	Subunit of γ complex, interacts with Ssb
	ψ	<i>holD</i>	15.2	Subunit of γ complex; links χ and γ
	β	<i>dnaN</i>	40.6	Processivity, sliding clamp
Primosome	Pri A (N')	<i>priA</i>	80	Recognition and binding to primosome assembly site (PAS), ATPase, helicase
	Pri B (N)	<i>priB</i>	11.4	stabilization of Pri A-PAS interaction
	Pri C (N'')	<i>priC</i>	20.3	Primosome assembly
	Dna T (I)	<i>dnaT</i>	20	Primosome assembly
	Dna G (primase)	<i>dnaG</i> (<i>parB</i>)	64	Primase, synthesizes RNA primer, interacts with DnaB
Ter (Tus, Tau)		<i>tus</i>	34	Contrahelicase, blocks Dna B by binding to Ter sites
HU	HU- α	<i>HupA</i>	10	Histone-like protein, condenses DNA
	HU- β	<i>HupB</i>	10	Forms heterodimer with HU- α
FIS		<i>fis</i>	11	Regulates initiation at <i>oriC</i> , small DNA-binding protein, modulates transcription factors and inversion
IHF	IHF- α	<i>himA</i>	11	Modulates initiation at <i>oriC</i> , involved in site-specific recombination
	IHF- β	<i>himD</i>	10	Forms heterodimer with IHF- α
Polymerase I		<i>polA</i>	103	Eliminates Okazaki primers, DNA repair polymerase
DNA Ligase		<i>lig</i>	74	Joins DNA fragments during replication

clamp onto the DNA template. The physical and genetic evidence supporting dimerization of DNA polymerase III is in accordance with a structural model for replication. This is a so-called inch-worm, or trombone, model of DNA replication (Fig. 28.3). As indicated in the model, a dimer at the growing fork would allow coupling of rates of synthesis on the leading and lagging strands, i.e., the strand made continuously and the strand made discontinuously. Because the strand made discontinuously may require frequent initiation, one might expect synthesis of this nascent DNA strand to be slower. To prevent a discrepancy in growth rate between the strands, dimerization of the synthesis units for the two strands is a method for locking the rates in step. It is possible to do this by assuming that the DNA template for the lagging strand loops out in such a way as to provide permissible polarity for the nascent strand.

A key player in organizing the replisome (that is, the multi-protein complex that replicates the chromosome) appears to be the τ subunit, which has been shown to interact with both DnaB helicase and primase.

The coupling of pol III to DnaB explains the high level of processivity on the leading strand while allowing the other half of the pol III holoenzyme to cycle on and off the lagging strand during microinitiation.

IV. TERMINATION OF REPLICATION

The termination of DNA replication is complicated by topological problems created by the circular nature of the bacterial chromosome. The double-helical structure of the template DNA, given a semiconservative mode of DNA replication, results in two interwound chromosomes which must be unlinked by topoisomerases. Decatenation of the newly replicated chromosomes is accomplished primarily by topoisomerase IV, a double-stranded DNA topoisomerase that closely resembles DNA gyrase (topoisomerase II). Another problem is that bidirectional replication on a circular template must be coordinated so that the opposing replication forks meet and terminate DNA

FIGURE 28.3 Fork progression in *E. coli*. The dimeric structure of the DNA polymerase III holoenzyme couples leading and lagging strand DNA synthesis during replication. Leading strand synthesis (bottom strand) is continuous and processive, but lagging strand synthesis must reinitiate many times during replication of the chromosome. This constraint is due to the antiparallel nature of DNA and the ability of DNA polymerases to synthesize DNA only in the 5' \rightarrow 3' direction. As the replication fork progresses, new primers are synthesized by primase on the lagging strand. The asymmetrical γ complex loads a new β dimer onto the primed DNA template, and then the β complex associates with the core polymerase to extend DNA synthesis from the 3' end of the primer. DNA synthesis on the lagging strand proceeds only as far as the previously replicated Okazaki fragment, at which point the β subunit, along with the nascent DNA, is released from the core polymerase, allowing the next cycle of synthesis to initiate at the next primer.

synthesis at a defined location. Otherwise, part of the genome might be overreplicated.

A specific region of the chromosome, approximately directly opposite the origin on the *E. coli* map at the 30- to 32-min region, represents the termination region. This region is particularly sparse in genetic markers. A specific terminator protein, *ter* (or *Tus*), binds to sequences called *Ter* (or τ). *Ter* sequences are arrayed in the termination region in an inverted repeat configuration such that binding of *Tus* protein to *Ter* sequences confers a polarity to blockage of the replication fork. *Tus* protein has been described as a polar contrahelicase because its ability to inhibit *DnaB*, the replication fork-specific helicase, depends on the polarity of the *Ter* sequence with respect to the origin of replication. A replication fork is unimpeded by *Tus* bound to a *ter* sequence in the forward orientation, but it is blocked by *Tus* bound to a *ter* sequence in the reverse orientation. Because of the inverted configuration of *Ter* sites in the termination region, a replication fork that progresses through a forward-oriented *Ter* site will be stopped at the next reverse-oriented site. The termination region thus “traps” replication forks, ensuring that part of the genome is not overreplicated. *Bacillus subtilis* has evolved a similar mechanism, with a termination protein, RTP, that binds to specific inversely-oriented repeats, also called *Ter* sequences. Of note is the fact that the *E. coli* *Ter* sites are widely separated by approximately 350 kb, whereas the innermost oppositely oriented *Ter* sites in *B. subtilis* are only 59 bp apart. The basic strategy for termination in the two organisms is quite similar, but the molecular mechanisms appear to be different. DNA replication termination may also be a control for cell division.

DNA restriction and modification

Noreen E. Murray

University of Edinburgh

GLOSSARY

ATP and ATP hydrolysis Adenosine triphosphate (ATP) is a primary repository of energy that is released for other catalytic activities when ATP is hydrolyzed (split) to yield adenosine diphosphate.

bacteriophages (lambda and T-even) Bacterial viruses. Phage lambda (λ) is a temperate phage and therefore on infection of a bacterial cell one of two alternative pathways may result; either the lytic pathway in which the bacterium is sacrificed and progeny phages are produced or the temperate (lysogenic) pathway in which the phage genome is repressed and, if it integrates into the host chromosome, will be stably maintained in the progeny of the surviving bacterium. Phage λ was isolated from *Escherichia coli* K-12 in which it resided in its temperate (prophage) state. T-even phages (T2, T4, and T6) are virulent coliphages, that is, infection of a sensitive strain of *E. coli* leads to the production of phages at the inevitable expense of the host. T-even phages share the unusual characteristic that their DNA includes hydroxymethylcytosine rather than cytosine.

conjugation, conjugational transfer Gene transfer by conjugation requires cell-to-cell contact. Conjugative, or self-transmissible, plasmids such as the F factor of *E. coli* encode the necessary functions to mobilize one strand of their DNA with a defined polarity from an origin of transfer determined by a specific nick. The complementary strand is then made in the recipient cell. Some plasmids are transmissible but only on provision *in trans* of the necessary functions by a conjugative plasmid. A conjugative plasmid, such

as the F factor, can mobilize transfer of the bacterial genome following integration of the plasmid into the bacterial chromosome.

DNA methyltransferases Enzymes (MTases) that catalyze the transfer of a methyl group from the donor S-adenosylmethionine to adenine or cytosine residues in the DNA.

efficiency of plating This usually refers to the ratio of the plaque count on a test strain relative to that obtained on a standard, or reference, strain.

endonucleases Enzymes that can fragment polynucleotides by the hydrolysis of internal phosphodiester bonds.

Escherichia coli strain K-12 The strain used by Lederberg and Tatum in their discovery of recombination in *E. coli*.

glucosylation of DNA The DNA of T-even phages in addition to the pentose sugar, deoxyribose, contains glucose attached to the hydroxymethyl group of hydroxymethyl-cytosine. Glucosylation of the DNA is mediated by phage-encoded enzymes, but the host provides the glucose donor.

helicases Enzymes that separate paired strands of polynucleotides.

recombination pathway The process by which new combinations of DNA sequences are generated. The general recombination process relies on enzymes that use DNA sequence homology for the recognition of the recombining partner. In the major pathway in *E. coli*, RecBCD generates the DNA strands for transfer and RecA protein promotes synapsis. The RecBCD enzyme, also recognized as exonuclease V, enters DNA via a double-strand end.

It tracks along the DNA, promoting unwinding of the strands but, in response to a special nucleotide sequence termed Chi, it makes a nick, following which strand separation continues and the single-stranded DNA with a 3' end becomes available for synapsis with homologous DNA. *In vitro*, the mechanism by which RecBCD makes a DNA end is determined by the reaction conditions; its activity as a potent exonuclease is influenced by the relative concentrations of ATP and Mg ions.

SOS response DNA damage induces expression of a set of genes, the SOS genes, involved in the repair of DNA damage.

Southern transfer The transfer of denatured DNA from a gel to a solid matrix, such as a nitrocellulose filter, within which the denatured DNA can be maintained and hybridized to labeled probes (single-stranded DNA or RNA molecules). Fragments previously separated by electrophoresis through a gel may be identified by hybridization to a specific probe.

transformation The direct assimilation of DNA by a cell, which results in the recipient being changed genetically.

Awareness of the Biological Phenomenon of Restriction and Modification (R–M) grew from the observations of microbiologists that the host range of a bacterial virus (phage) was influenced by the bacterial strain in which the phage was last propagated. Although phages produced in one strain of *Escherichia coli* would readily infect a culture of the same strain, they might only rarely achieve the successful infection of cells from a different strain of *E. coli*. This finding implied that the phages carried an “imprint” that identified their immediate provenance. Simple biological tests showed that the occasional successful infection of a different strain resulted in the production of phages that had lost their previous imprint and had acquired a new one.

In the 1960s, elegant molecular experiments showed the “imprint” to be a DNA modification that was lost when the phage DNA replicated within a different bacterial strain; those phages that conserved one of their original DNA strands retained the imprint, or modification, whereas phages containing two strands of newly synthesized DNA did not. The modification was shown to provide protection against an endonuclease, the barrier that prevented the replication of incoming phage genomes. Later it was proven that the modification and restriction enzymes both recognized the same target, a specific nucleotide sequence. The modification enzyme was a DNA methyltransferase that methylated specific

bases within the target sequence, and in the absence of the specific methylation the target sequence rendered the DNA sensitive to the restriction enzyme. When DNA lacking the appropriate modification imprint enters a restriction-proficient cell it is recognized as foreign and degraded by the endonuclease. The host-controlled barrier to successful infection by phages that lacked the correct modification was referred to as “restriction” and the relevant endonucleases have acquired the colloquial name of restriction enzymes. Similarly, the methyltransferases are more commonly termed modification enzymes. Classically, a restriction enzyme is accompanied by its cognate modification enzyme and the two comprise a R–M system. Most restriction systems conform to this classical pattern. There are, however, some restriction endonucleases that attack DNA only when their target sequence is modified. A restriction system that responds to its target sequence only when it is identified by modified bases does not, therefore, co-exist with a cognate modification enzyme.

Two early papers documented the phenomenon of restriction. In one, Bertani and Weigle (1953), using temperate phages (λ and P2), identified the classical restriction and modification systems characteristic of *E. coli* K-12 and *E. coli* B. In the other, Luria and Human (1952) identified a restriction system of the second, nonclassical kind. In the experiments of Luria and Human, T-even phages were used as test phages, and after their growth in a mutant *E. coli* host they were found to be restricted by wild-type *E. coli* K-12 but not by *Shigella dysenteriae*. An understanding of the restriction phenomenon observed by Luria and Human requires knowledge of the special nature of the DNA of T-even phages. During replication of T-even phages the unusual base 5-hydroxymethylcytosine (HMC) completely substitutes for cytosine in the T-phage DNA, and the hydroxymethyl group is subsequently glucosylated in a phage-specific pattern at the polynucleotide level. In the mutant strain of *E. coli* used by Luria and Human as host for the T-even phages, glucosylation fails and, in its absence, the nonglucosylated phage DNA becomes sensitive to an endonuclease present in *E. coli* K-12 but not in *S. dysenteriae*. Particular nucleotide sequences normally protected by glu cosylation are recognized by an endonuclease in *E. coli* K-12 when they include the modified base, HMC, rather than cytosine residues. In the T-phage experiments the modified base is hydroxymethyl-cytosine, but much later it was discovered that methylated cytosine residues can also evoke restriction by the same endonucleases.

The classical (R–M) systems and the modification-dependent restriction enzymes share the potential to

attack DNA derived from different strains and thereby "restrict" DNA transfer. They differ in that in one case an associated modification enzyme is required to protect DNA from attack by the cognate restriction enzyme and in the other modification enzymes specified by different strains impart signals that provoke the degradative activity of restriction endonucleases.

I. DETECTION OF RESTRICTION SYSTEMS

A. As a barrier to gene transfer

This is exemplified by the original detection of the R-M systems of *E. coli* K-12 and *E. coli* B by Bertani and Weigle in 1953. Phage λ grown on *E. coli* strain C (λ .C), where *E. coli* C is a strain that apparently lacks an R-M system, forms plaques with poor efficiency of plating (EOP) of 2×10^{-4} on *E. coli* K-12 because the phage DNA is attacked by a restriction endonuclease (Fig. 29.1). Phage λ grown on *E. coli* K-12 (λ .K) forms plaques with equal efficiency on *E. coli* K-12 and *E. coli* C since it has the modification required to protect against the restriction system of *E. coli* K-12 and *E. coli* C has no restriction system (Fig. 29.1). In contrast, λ .K will form plaques with very low efficiency on a third strain, *E. coli* B, since *E. coli* B has an R-M system with different sequence specificity from that of *E. coli* K-12.

Phages often provide a useful and sensitive test for the presence of R-M systems in laboratory strains of

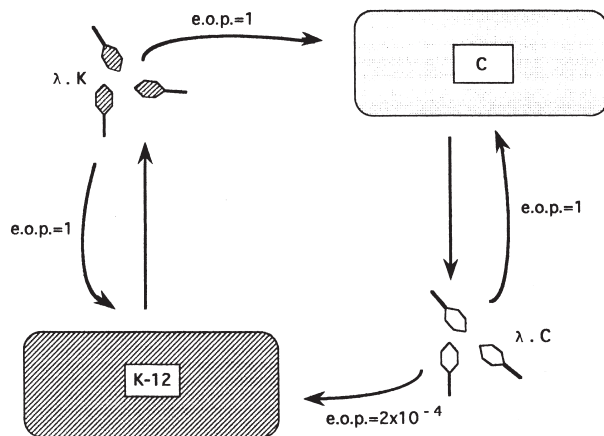

FIGURE 29.1 Host-controlled restriction of bacteriophage λ . *Escherichia coli* K-12 possesses, whereas *E. coli* C lacks, a Type I R-M system. Phage λ propagated in *E. coli* C (λ .C) is not protected from restriction by *Eco* KI and thus forms plaques with reduced efficiency of plating (EOP) on *E. coli* K-12 as compared to *E. coli* C. Phages escaping restriction are modified by the *Eco* KI methyltransferase (λ .K) and consequently form plaques with the same efficiency on *E. coli* K-12 and C. Modified DNA is indicated by hatch marks (reproduced with permission from Barcus and Murray, 1995).

bacteria, but they are not a suitable vehicle for the general detection of barriers to gene transfer. Many bacterial strains, even within the same species and particularly when isolated from natural habitats, are unable to support the propagation of the available test phages, and some phages (e.g. P1) have the means to antagonize at least some restriction systems (see Section IV.C). Gene transfer by conjugation can monitor restriction although some natural plasmids, but probably not the F factor of *E. coli*, are equipped with antirestriction systems. The single-stranded DNA that enters a recipient cell by conjugation, or following infection by a phage such as M13, becomes sensitive to restriction only after the synthesis of its complementary second strand, whereas the single-stranded DNA that transforms naturally competent bacteria may not become a target for restriction because it forms heteroduplex DNA with resident (and therefore modified) DNA and one modified strand is sufficient to endow protection. Transformation can be used to detect restriction systems, but only when the target DNA is the double-stranded DNA of a plasmid.

B. *In vitro* assays for DNA fragmentation

Endonuclease activities yielding discrete fragments of DNA are commonly detected in crude extracts of bacterial cells. More than one DNA may be used to increase the chance of providing a substrate that includes target sequences. DNA fragments diagnostic of endonuclease activity are separated according to their size by electrophoresis through a matrix, usually an agarose gel, and are visualized by the use of a fluorescent dye, ethidium bromide, that intercalates between stacked base pairs.

Extensive screening of many bacteria, often obscure species for which there is no genetic test, has produced a wealth of endonucleases with different target sequence specificities. These endonucleases are referred to as restriction enzymes, even in the absence of biological experiments to indicate their role as a barrier to the transfer of DNA. Many of these enzymes are among the commercially available endonucleases that serve molecular biologists in the analysis of DNA (Table 29.1; see Section VII). *In vitro* screens are applicable to all organisms, but to date restriction and modification systems have not been found in eukaryotes, although some algal viruses encode them.

C. Sequence-specific screens

The identification of new R-M genes via sequence similarities is sometimes possible. Only occasionally are gene sequences sufficiently conserved that the

^b1, produces blunt ends; 2, produces cohesive ends with 5' single-stranded overhangs; 3, cohesive ends of *Sau*3AI and *Bam*HI are identical; 4, produces cohesive ends with 3' single-stranded overhangs; 5, Pu is any purine (A or G), and Py is any pyrimidine (C or T).

presence of related systems can be detected by probing Southern transfers of bacterial DNA. Generally, screening databases of predicted polypeptide sequences for relevant motifs has identified putative R–M systems in the rapidly growing list of bacteria for which the genomic sequence is available. Currently, this approach is more dependable for modification methyltransferases than for restriction endonucleases, but the genes encoding the modification and restriction enzymes are usually adjacent. Many putative R–M systems have been identified in bacterial genomic sequences.

II. NOMENCLATURE AND CLASSIFICATION

A. Nomenclature

R–M systems are designated by a three-letter acronym derived from the name of the organism in which they occur. The first letter is derived from the genus and the second and third letters from the species. The strain designation, if any, follows the acronym.

Different systems in the same organism are distinguished by Roman numerals. Thus, *Hind*II and *Hind*III are two enzymes from *Hemophilus influenzae* strain Rd. Restriction endonuclease and modification methyltransferases (ENases and MTases) are sometimes distinguished by the prefixes R. *Eco*RI and M. *Eco*RI, but the prefix is commonly omitted if the context is unambiguous.

B. Classification of R–M systems

R–M systems are classified according to the composition and cofactor requirements of the enzymes, the nature of the target sequence, and the position of the site of DNA cleavage with respect to the target sequence. Currently, three distinct, well-characterized types of classical R–M systems are known (I–III), although a few do not share all the characteristics of any of these three types. In addition, there are modification-dependent systems. Type I systems were identified first, but the Type II systems are the simplest and for this reason will be described first. A summary of the properties of different types of R–M systems is given in Fig. 29.2.

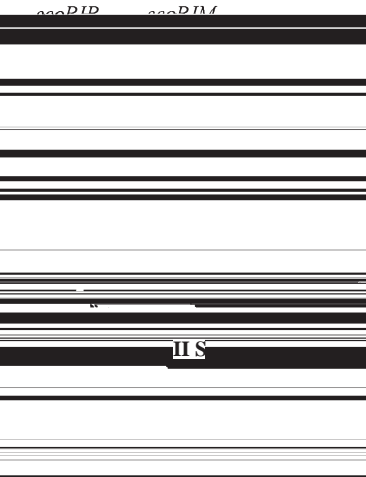

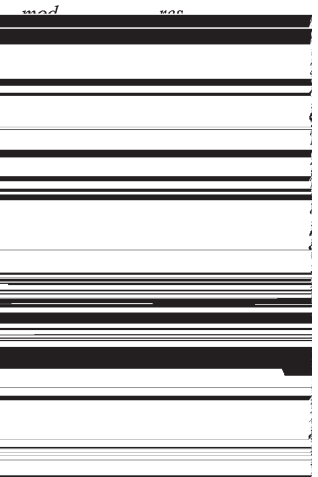

Type I	Type II	Type III

FIGURE 29.2 The distinguishing characteristics and organization of the genetic determinants and subunits of the different types of restriction and modification (R–M) systems. R–M systems are classified on the basis of their complexity, cofactor requirements, and position of DNA cleavage with respect to their DNA target sequence. The Types I–III systems are the classical R–M systems. The restriction enzymes of the Types I and III systems contain motifs characteristic of DEAD-box proteins and may therefore be helicases. Helicase activity could be associated with DNA translocation. The Type II S systems are a subgroup of the Type II systems that cleave DNA outside their recognition sequence. Some systems do not fit readily into the current classification (See Roberts *et al.*, 2003 for an updated classification of anomolous systems). The modification-dependent systems are not classical R–M systems, because they have no cognate methylase and only cut DNA that contains certain modifications. ENase, restriction endonuclease; MTase, methyltransferase (reprinted from *Trends in Microbiology* 2 (12), G. King and N. E. Murray, pp. 461–501. Copyright 1995, with permission from Elsevier Science).

C. Type II R–M systems

A Type II R–M system comprises two separate enzymes; one is the restriction ENase and the other the modification MTase. The nuclease activity requires Mg^{2+} , and DNA methylation requires S-adenosylmethionine (AdoMet) as methyl donor. The target sequence of both enzymes is the same; the modification enzyme ensures that a specific base within the target sequence, one on each strand of the duplex, is methylated and the restriction endonuclease cleaves unmodified substrates within, or close to, the target sequence. The target sequences are usually rotationally symmetrical sequences of from 4 to 8 bp; for example, a duplex of the sequence 5' -GAA*TTC is recognized by *EcoRI*. The modification enzyme methylates the adenine residue identified by the asterisk, but in the absence of methylated adenine

residues on both strands of the target sequence the restriction endonuclease breaks the phosphodiester backbones of the DNA duplex to generate ends with 3' hydroxyl and 5' phosphate groups. The Type II systems can be subdivided according to the nature of the modification introduced by the MTase: N6-methyladenine (m6A) and N5 and N4 methylcytosine (m5C and m4C). Irrespective of the target sequence or the nature of the modification, ENases differ in that some cut the DNA to generate ends with 5' overhangs, some generate 3' overhangs, and others produce ends which are "blunt" or "flush" (Table 29.1).

Type II restriction enzymes are generally active as symmetrically arranged homodimers, an association that facilitates the coordinated cleavage of both strands of the DNA. In contrast, Type II modification enzymes act as monomers, an organization consistent

with their normal role in the methylation of newly replicated DNA in which one strand is already methylated.

The genes encoding Type II R–M systems derive from the name of the system. The genes specifying R. *Bam*HI and M. *Bam*HI, for example, are designated *bamHIR* and *bamHIM*. Transfer of the gene encoding a restriction enzyme in the absence of the transfer of the partner encoding the protective MTase is likely to be lethal if the recipient cell does not provide the relevant protection. Experimental evidence supports the expectation that the genes encoding the two components of R–M systems are usually closely linked so that cotransfer will be efficient.

A subgroup of Type II systems, Type IIS, recognizes asymmetric DNA sequences of 4–7bp in length. These ENases cleave the DNA at a precise but short distance outside their recognition sequence; their name is derived from their shifted (S) position of cutting. Type IIS systems have simple cofactor requirements and comprise two separate enzymes, but they differ from classical Type II systems in the recognition of an asymmetric DNA sequence by a monomeric ENase, and require two MTase activities, but see Roberts *et al.* (2003) for the current classification of unusual Type II R–M systems.

D. Type I R–M systems

Type I R–M systems are multifunctional enzymes comprising three subunits that catalyze both restriction and modification. In addition to Mg^{2+} , endonucleolytic activity requires both AdoMet and adenosine triphosphate (ATP). The restriction activity of Type I enzymes is associated with the hydrolysis of ATP, an activity that may correlate with the peculiar characteristic of these enzymes—that of cutting DNA at non-specific nucleotide sequences at considerable distances from their target sequences. The Type I R–M enzyme binds to its target sequence and its activity as an ENase or a MTase is determined by the methylation state of the target sequence. If the target sequence is unmodified, the enzyme, while bound to its target site, is believed to translocate (move) the DNA from both sides toward itself in an ATP-dependent manner. This translocation process brings the bound enzymes closer to each other and experimental evidence suggests that DNA cleavage occurs when translocation is impeded, either by collision with another translocating complex or by the topology of the DNA substrate.

The nucleotide sequences recognized by Type I enzymes are asymmetric and comprise two components, one of 3 or 4 bp and the other of 4 or 5 bp, separated by a non-specific spacer of 6–8bp. All known Type I enzymes methylate adenine residues, one on each strand of the target sequence.

The subunits of a Type I R–M enzyme are encoded by three genes: *hsdR*, *hsdM*, and *hsdS*. The acronym *hsd* was chosen at a time when R–M systems were referred to as host specificity systems, and *hsd* denotes host specificity of DNA. The three *hsd* genes are usually contiguous, but not always in the same order. *hsdM* and *hsdS* are transcribed from the same promoter, but *hsdR* is from a separate one. The two subunits encoded by *hsdM* and *hsdS*, sometimes referred to as M and S, are both necessary and sufficient for MTase activity. The third subunit (R) is essential only for restriction. The S (specificity) subunit includes two target recognition domains (TRDs) that impart target sequence specificity to both restriction and modification activities of the complex; the M subunits include the binding site for AdoMet and the active site for DNA methylation. Two complexes of Hsd subunits are functional in bacterial cells: one comprises all three subunits ($R_2M_2S_1$) and is an R–M system, and the other lacks R (M_2S_1) and has only Mtase activity.

E. Type III R–M systems

Type III R–M systems are less complex than Type I systems but nevertheless share some similarities with them. A single heterooligomeric complex catalyzes both restriction and modification activities. Modification requires the cofactor AdoMet and is stimulated by Mg^{2+} and ATP. Restriction requires Mg^{2+} and ATP and is stimulated by AdoMet. The recognition sequences of Type III enzymes are asymmetric sequences of 5 or 6bp. Restriction requires two unmodified sequences in inverse orientation (Fig. 29.3a). Recent evidence indicates that Type III R–M enzymes, like those of Type I, can translocate DNA in a process dependent on ATP hydrolysis, but they hydrolyze less ATP than do Type I systems and probably only translocate DNA for a relatively short distance. Cleavage is stimulated by collision of the translocating complexes and occurs on the 3' side of the recognition sequence at a distance of approximately 25–27 bp. This contrasts with cleavage by Type I enzymes in which cutting occurs at sites remote from the recognition sequence. Because only one strand of the recognition sequence of a Type III R–M system is a substrate for methylation, it might be anticipated that the immediate product of replication would be sensitive to restriction. It is necessary to distinguish the target for modification from that needed for restriction in order to understand why this is not so. Restriction is only elicited when two unmethylated target sequences are in inverse orientation with respect to each other and, as shown in Fig. 29.3b, replication of modified DNA leaves all unmodified targets in the

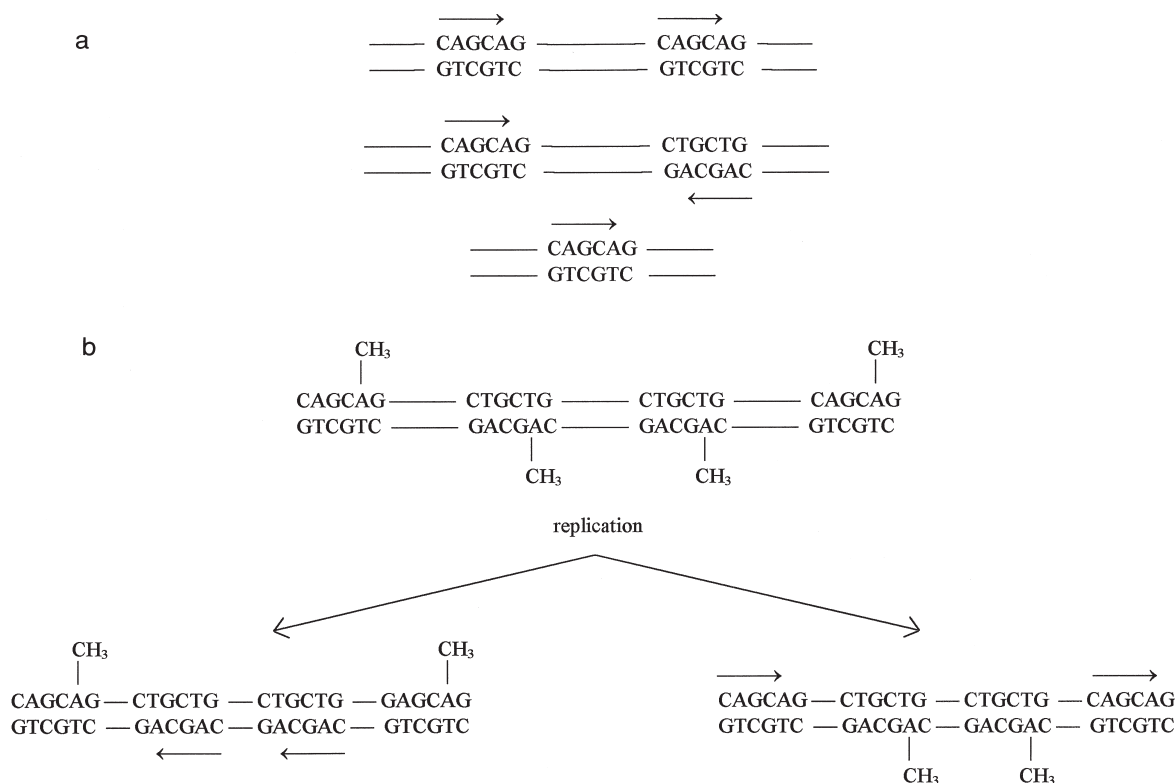

FIGURE 29.3 DNA substrates for a Type III R–M system (*EcoP15I*). The top strand of each duplex is written 5' to 3' the arrows identify the orientation of the target sequences. Solid lines indicate polynucleotide chains of undefined sequence. (a) Only pairs of target sequences shown in inverse orientation (line 2) are substrates for restriction. A single site in any orientation is a target for modification. (b) Replication of modified DNA leaves all unmodified target sites in the daughter molecules in the same orientation, and therefore insensitive to restriction.

same orientation. When two targets are appropriately positioned in close proximity, cutting can be elicited in the absence of DNA translocation.

The bifunctional R–M complex is made up of two subunits, the products of the *mod* and *res* genes. The Mod subunit is sufficient for modification, whereas the Res and Mod subunits together form a complex with both activities (Fig. 29.2). The Mod subunit is functionally equivalent to the MTase (M_2S) of Type I systems and, as in Type I R–M systems, imparts sequence specificity to both activities.

F. Modification-dependent restriction systems

These systems only cut modified DNA. They are variable in their complexity and requirements. The simplest is *DpnI* from *Streptococcus pneumoniae* (previously called *Diplococcus pneumoniae*). The ENase is encoded by one gene, and the protein looks and behaves like a Type II enzyme except that it only cuts its target sequence when it includes methylated adenine residues.

Escherichia coli K-12 encodes three other distinct, sequence specific, modification-dependent systems.

Two, *Mrr* and *McrA*, are specified by single genes. *Mrr* is distinguished by its ability to recognize DNA containing either methylated adenine or 5-methylcytosine in the context of particular, but undefined, sequences. *McrA* and *McrBC* both restrict DNA containing modified cytosines (hydroxymethylcytosine or methylcytosine). The *mcr* systems (modified cytosine restriction) are those first recognized by Luria and Human by their ability to restrict nonglycosylated T-even phages (*rglA* and *B*; restricts glucose-less phage). *McrBC* is a complex enzyme with a requirement for GTP rather than ATP. *McrBC*, like the ATP-dependent restriction enzymes, translocates DNA.

G. Other systems

As more R–M systems are identified, new enzymes with novel properties continue to be found. *Eco571* and *BcgI*, for example, are most similar to Type II systems, but are not ideally suited to this classification (Fig. 29.2). *Eco571* comprises a joint ENase–MTase and a separate MTase. The former behaves as if it were a Type IIS endonuclease fused to a MTase; it cleaves to one side of the target sequence and methylates the

sequence on one strand. Cleavage is stimulated by AdoMet but not by ATP. The separate MTase behaves like a Type II modification enzyme.

III. R–M ENZYMES AS MODEL SYSTEMS

A. Enzyme activities, sequence recognition, including base flipping

Structures of the crystals of several Type II restriction ENases have been determined, some in both the presence and the absence of DNA. The symmetrically arranged dimers of the Type II enzymes interact with their specific target sequences by the combined effects of different types of interactions including hydrogen bonding and electrostatic interactions of amino acid residues with the bases and the phosphate backbone of the DNA. No general structure, such as a helix-turn-helix or zinc finger (often found in proteins that interact with DNA) defines the sequence-specific interactions with the DNA, and amino acids that are widely separated in the primary sequence may be involved in interactions with the target nucleotide sequence. Three-dimensional structures of Type II restriction endonucleases show that their catalytic centers share a common structural core comprising four β -strands and an α -helix. Comparisons of the active sites of *EcoRV*, *EcoRI*, and *PvuII* identify a conserved tripeptide sequence close to the target phosphodiester group and a conserved acidic dipeptide that represent the ligands for the catalytic cofactor Mg^{2+} essential for ENase activity. These two sequences are also relevant to the active site for Type I restriction endonucleases.

The structure of a monomeric MTase interacting with its target sequence provided an important solution to the question of how enzymes that modify a base within a DNA molecule can reach their substrate. The cocrystal structure of *M. HhaI* bound to its substrate showed that the target cytidine rotates on its sugar-phosphate bonds such that it projects out of the DNA and fits into the catalytic pocket of the enzyme. Such base flipping was confirmed for a second enzyme, *M. HaeIII*, which also modifies cytosine, and circumstantial evidence supports the notion that this mechanism may be true for all MTases regardless of whether they methylate cytosine or adenine residues.

Comparative analyses of the amino acid sequences of many MTases identified a series of motifs, many of which are common to MTases irrespective of whether the target base is cytosine or adenine. These motifs enable structural predictions to be made about the

catalytic site for DNA methylation in complex enzymes for which crystals are not available.

B. DNA translocation

Specific interactions of large R–M enzymes with their DNA substrates are not readily amenable to structural analysis. The relative molecular weight of *EcoKI* is in excess of 400,000 and useful crystals have not been obtained. Nevertheless, these complex enzymes have other features of mechanistic interest. Much evidence supports models in which DNA restriction involves the translocation of DNA in an ATP-dependent process prior to the cutting of the substrate. In the case of Type I R–M enzymes, the breaks in the DNA may be many kilobases remote from the target sequence. Molineux *et al.* (See Murray, 2002), using assays with phages, have shown that *EcoKI* can transfer (translocate) the entire genome (39 kb) of phage T7 from its capsid to the bacterial cell. For linear DNA, the evidence supports the idea that cutting by Type I R–M systems occurs preferentially midway between two target sequences. For Type III enzymes the breaks are close to the target sequence, but in both cases the endonuclease activity may be stimulated by the collision of two translocating protein complexes.

The most conserved features of the polypeptide sequences of Type I and Type III R–M systems are the motifs characteristic of adenine MTases and the so-called DEAD-box motifs found in RNA and DNA helicases. The latter motifs acquired their collective name because a common variant of one element is Asp-Glu-Ala-Asp, or DEAD when written in a single-letter code. The DEAD-box motifs, which include sequences diagnostic of ATP binding, are found in the subunit that is essential for restriction (HsdR or Res) but not for modification. It is not known whether an ATP-dependent helicase activity drives the translocation of DNA, although circumstantial evidence correlates ATPase activity with DNA translocation. Mutations in each DEAD-box motif have been shown to impair the ATPase and endonuclease activities of a Type I ENase.

IV. CONTROL AND ALLEVIATION OF RESTRICTION

A. Control of gene expression

The expression of genes coding for R–M systems requires careful regulation. Not only is this essential to maintain the protection of host DNA in restriction-proficient

cells but also it is especially important when R–M genes enter a new host. Experiments show that many R–M genes are readily transferred from one laboratory strain to another. The protection of host DNA against the endonucleolytic activity of a newly acquired restriction system can be achieved if the functional cognate MTase is produced before the restriction enzyme. Representatives of all three types of classical R–M systems have been shown to be equipped with promoters that might permit transcriptional regulation of the two activities.

Transcriptional regulation of some of the genes encoding Type II systems has been demonstrated. Genes encoding repressor-like proteins, referred to as C-proteins for controlling proteins, have been identified in some instances. The C-protein for the *Bam*HI system has been shown to activate efficient expression of the restriction gene and modulate the expression of the modification gene. When the R–M genes are transferred to a new environment, in the absence of C-protein there will be preferential expression of the modification gene, and only after the production of the C-protein will the cells become restriction proficient.

For complex R–M systems, despite the presence of two promoters, there is no evidence for transcriptional regulation of gene expression. The heterooligomeric nature of these systems presents the opportunity for the regulation of the restriction and modification activities by the intracellular concentrations of the subunits and the affinities with which different subunits bind to each other. Nevertheless, efficient transmission of the functional R–M genes of some Type I systems requires ClpX and ClpP in the recipient cell. Together these proteins comprise a protease, but ClpX has chaperone activity (i.e. an ability to help other proteins to fold correctly). These proteins function to permit the acquisition of new R–M systems; they degrade the HsdR subunit of active R–M complexes before the endonuclease activity has the opportunity to cleave unmodified DNA.

B. Restriction alleviation

The efficiency with which a bacterial cell restricts unmodified DNA is influenced by a number of stimuli, all of which share the ability to damage DNA. DNA damage provokes the induction of the SOS response, and one consequence of this is a marked reduction in the efficiency with which *E. coli* K-12 restricts incoming DNA. This alleviation of restriction is usually monitored by following the EOP of phages—unmodified in the case of classical systems or modified in the case of modification-dependent restriction

systems. Alleviation of restriction is characteristic of complex systems and can be induced by ultraviolet light, nalidixic-acid, 2-aminopurine, and the absence of Dam-mediated methylation. The effect can be appreciable and a variety of host systems contribute to more than one pathway of alleviation. Recent experiments have shown for *Eco*KI that ClpXP is necessary for restriction alleviation; therefore there appears to be a connection between the complex mechanisms by which restriction activity is normally controlled and its alleviation in response to DNA damage.

C. Antirestriction systems

Many phages and some conjugative plasmids specify functions that antagonize restriction. An apparent bias of functions that inhibit restriction by Type I R–M systems may reflect the genotype of the classical laboratory strain *E. coli* K-12, which is a strain with a Type I but no Type II R–M system.

The coliphages T3 and T7 include an “early” gene, *O.3*, or *ocr*, the product of which binds Type I R–M enzymes and abolishes both restriction and modification activities. *O.3* protein does not affect Type II systems. The *O.3* gene is expressed before targets in the phage genome are accessible to host restriction enzymes so that *O.3*⁺ phages are protected from restriction and modification by Type I systems. Phage T3 *O.3* protein has an additional activity; it hydrolyzes AdoMet, the cofactor essential for both restriction and modification by *Eco*KI and its relatives. Bacteriophage P1 also protects its DNA from Type I restriction, but the antirestriction function Dar does not interfere with modification. The Dar proteins are coinjected with encapsidated DNA so that any DNA packaged in a P1 head is protected. This allows efficient generalized transduction to occur between strains with different Type I R–M systems.

Coliphage T5 has a well-documented system for protection against the Type II system *Eco*RI. As with the *O.3* systems of T3 and T7, the gene is expressed early when the first part of the phage genome enters the bacterium. This first segment lacks *Eco*RI targets, whereas the rest of the genome, which enters later, has targets that would be susceptible in the absence of the antirestriction protein.

Some conjugative plasmids of *E. coli*, members of the incompatibility groups I and N, also encode antirestriction functions. They are specified by the *ard* genes located close to the origin of DNA transfer by conjugation so that they are among the first genes to be expressed following DNA transfer. Like the *O.3* proteins of T3 and T7, the protein encoded by *ard* is active against Type I R–M systems.

Bacteriophage λ encodes a very specialized anti-restriction function, Ral, which modulates the *in vivo* activity of some Type I R–M systems by enhancing modification and alleviating restriction. The systems influenced by Ral are those that have a modification enzyme with a strong preference for hemimethylated DNA. Ral may act by changing the MTase activity of the R–M system to one that is efficient on unmethylated target sequences. Unmodified *ral*⁺ λ DNA is restricted on infection of a restriction-proficient bacterium, because *ral* is not normally expressed before the genome is attacked by the host R–M system, but phages that escape restriction and express *ral* are more likely to become modified as Ral serves to enhance the efficiency with which the modification enzyme methylates unmethylated DNA.

Some phages are made resistant to many types of R–M systems by the presence of glucosylated hydroxymethylcytosine (HMC) in their DNA (e.g. the *E. coli* T-even phages and the *Shigella* phage DDVI). The glucosylation also identifies phage DNA and allows selective degradation of host DNA by phage-encoded nucleases. Nonglucosylated T-even phages are resistant to some classical R–M systems because their DNA contains the modified base HMC, but they are sensitive to modification-dependent systems, although T-even phages encode a protein (Arn) that protects superinfecting phages from McrBC restriction. It has been suggested that phages have evolved DNA containing HMC to counteract classical R–M systems, and that host-encoded modification-dependent endonucleases are a response to this phage adaptation. In this evolutionary story, the glucosylation of HMC would be the latest mechanism that renders T-even phages totally resistant to most R–M systems.

In some cases, a phage genome can tolerate a few targets for certain restriction enzymes. The few *EcoRII* sites in T3 and T7 DNA are not sensitive to restriction because this unusual enzyme requires at least two targets in close proximity and the targets in these genomes are not sufficiently close. For the Type III enzymes, the orientation of the target sequences is also relevant. Since the target for restriction requires two inversely oriented recognition sequences, the T7 genome remains refractory to *EcoP151* because all 36 recognition sequences are in the same orientation. The unidirectional orientation of the target sequences is consistent with selection for a genome that will avoid restriction. Considerable evidence supports the significance of counterselection of target sequences in phage genomes, in some cases correlating the lack of target sequences for enzymes found in those hosts in which the phages can propagate.

V. DISTRIBUTION, DIVERSITY, AND EVOLUTION

A. Distribution and diversity

R–M systems are almost ubiquitous among prokaryotes. Over 3000 have been identified. The most complete documentation is that for Type II systems. This is a result of the many *in vitro* screens for sequence-specific endonucleases put to effective use in the search for enzymes with different specificities. The endonucleases identified include more than 200 different sequence specificities. Type II restriction enzymes have been detected in 12 of the 13 phyla of Bacteria and Archaea. The lack of representation in one phylum, Chlamydia, could result from a sampling bias, but it could reflect the fact that the available genomic sequences are from parasitic species that grow within eukaryotic cells.

There is no reliable biological screen for Type I systems and there has been no practical incentive to search for enzymes that cut DNA at variable distances from their recognition sequence. The apparent prevalence of Type I systems in enteric bacteria may simply reflect the common use of *E. coli* and its relatives in genetic studies. Genetic tests currently provide evidence for Type I enzymes with approximately 20 different specificities, and recent analyses of genomic sequences from diverse species indicate that Type I systems are widely distributed throughout the prokaryotic kingdom.

Janulaitis and colleagues screened natural isolates of *E. coli* for sequence-specific ENases and detected activity in 25% of nearly 1000 strains tested. Another screening experiment searched for restriction activity encoded by transmissible resistance plasmids in *E. coli*. The plasmids were transferred to *E. coli* and the EOP of phage λ was determined on the exconjugants. Approximately 10% of the transmissible antibiotic resistance plasmids were correlated with the restriction of λ and the ENases responsible were shown to be Type II. However, plasmid-borne Type I, Type II, and Type III systems are known in *E. coli*. Because of the transmissible nature of many plasmids, the frequency with which R–M systems are transferred between strains could be high and their maintenance subject to a variety of selection pressures not necessarily associated with the restriction phenotype.

The evidence, where available (i.e. for *E. coli* and *Salmonella enterica*), is consistent with intraspecific diversity irrespective of the level at which the diversity is examined. In *E. coli*, there are at least six distinct mechanistic classes of restriction enzyme (types I–III, and three modification-dependent types) and the

anomalous *Eco571* (Fig. 29.2). The Type II systems in *E. coli* currently include approximately 30 specificities, and at least 14 Type I specificities have been identified. Bacterial strains frequently have more than one active restriction system. Four systems are present in *E. coli* K-12, and *H. influenzae* Rd has at least three systems that are known to be biologically active, whereas three more are indicated in the genomic sequence.

Genome sequences now provide a wealth of information about the distribution of coding sequences for R–M systems; these do not necessarily indicate whether the genes specify active enzymes.

B. Evolution

R–M enzymes may be dissected into modules. A Type II MTase comprises a TRD and a module that is responsible for catalyzing the transfer of the methyl group from AdoMet to the defined position on the relevant base. The catalytic domains share sequence similarities, and these are most similar when the catalytic reaction is the same, that is, yields the same product (e.g. 5 mC). Given the matching specificities of cognate ENase and MTase, it might be expected that their TRDs would be of similar amino acid sequence. This is not the case; it seems likely that the two enzymes use different strategies to recognize their target sequence. Each subunit of the dimeric ENase needs to recognize one-half of the rotationally symmetrical sequence, whereas the monomeric MTase must recognize the entire sequence. The absence of similarity between the TRDs of the ENase and its cognate MTase suggests that they may have evolved from different origins.

Restriction enzymes that recognize the same target sequence are referred to as isoschizomers. A simple expectation is that the TRDs of two such enzymes would be very similar. This is not necessarily true. Furthermore, the similarities observed do not appear to correlate with taxonomic distance. The amino acid sequences of the isoschizomers *HaeIII* and *NgoPII*, which are from bacteria in the same phylum, show little if any similarity, whereas the isoschizomers *FnuDI* and *NgoPII*, which are isolated from bacteria in different phyla, are very similar (59% identity).

Type I R–M systems are complex in composition and cumbersome in their mode of action, but they are well suited for the diversification of sequence specificity. A single subunit (HsdS or S) confers specificity to the entire R–M complex and to the additional smaller complex that is an MTase. Any change in specificity affects restriction and modification concomitantly. Consistent with their potential to evolve new specificities, Type I systems exist as families, within which members (e.g. *EcoKI* and *EcoBI*) are

distinguished only by their S subunits. Currently, allelic genes have been identified for at least seven members of one family (IA); each member has a different specificity. It is more surprising that allelic genes in *E. coli*, and its relatives, also specify at least two more families of Type I enzymes. Although members of a family include only major sequence differences in their S polypeptides, those in different families share very limited sequence identities (usually 18–30%). Clearly, the differences between gene sequences for Type I R–M systems are no indication of the phylogenetic relatedness of the strains that encode them. Note that despite the general absence of sequence similarities between members of different families of Type I enzymes, pronounced similarities have been identified for TRDs from different families when they confer the same sequence specificity.

The information from gene sequences for both Type I and Type II systems, as stated by Raleigh and Brooks (1998), “yields a picture of a pool of genes that have circulated with few taxonomic limitations for a very long time.”

Allelic variability is one of the most striking features of Type I R–M systems. Both the bipartite and asymmetrical natures of the target sequence confer more scope for diversity of sequence specificity than the symmetrical recognition sequences of Type II systems. The S subunit of Type I enzymes includes two TRDs, each specifying one component of the target sequence. This organization of domains makes the subunit well suited to the generation of new specificities as the consequences of either new combinations of TRDs or minor changes in the spacing between TRDs. In the first case, recombination merely reassembles the regions specifying the TRDs, and in the second case unequal crossing over within a short duplicated sequence leads to a change in the spacing between the TRDs. Both of these processes have occurred in the laboratory by chance and by design.

For Type I R–M systems, the swapping or repositioning of domains can create enzymes with novel specificities, but the evolution of new TRDs with different specificities has not been witnessed. In one experiment, strong selection for a change that permitted a degeneracy at one of the seven positions within the target sequence failed to yield mutants with a relaxed specificity.

VI. BIOLOGICAL SIGNIFICANCE

The wide distribution and extraordinary diversity of R–M systems, particularly the allelic diversity

documented in enteric bacteria, suggest that R–M systems have an important role in bacterial communities. This role has traditionally been considered to be protection against phage. Laboratory studies following bacterial populations under conditions of phage infection indicate that R–M systems provide only a transitory advantage to bacteria. Essentially, an R–M system with a different specificity could assist bacteria in the colonization of a new habitat in which phage are present, but this advantage would be short-lived as phages that escape restriction acquire the new protective modification and bacteria acquire mutations conferring resistance to the infecting phages. It can be argued that one R–M system protects against a variety of phages, and the maintenance of one R–M system may compromise the fitness of the bacterium less than the multiple mutations required to confer resistance to a variety of phages. No direct evidence supports this expectation. It is relevant to remember that the restriction barrier is generally incomplete, irrespective of the mechanism of DNA transfer, and that the fate of phage and bacterial DNA fragmented by ENases may differ. A single cut in a phage genome is sufficient to prevent infectivity. Fragments generated from bacterial DNA will generally share homology with the host chromosome and could therefore be rescued by recombination. The rescue of viable phages by homologous recombination requires infection by more than one phage or recombination with phage genomes that reside within the host chromosome. A protective role for R–M systems in no way excludes an additional role that influences genetic recombination.

In *E. coli*, and probably bacteria in general, linear DNA fragments are vulnerable to degradation by exonucleases, particularly ExoV (RecBCD). Therefore, the products of restriction are substrates for degradation by the same enzyme that is an essential component of the major recombination pathway in *E. coli*. However, degradation by RecBCD is impeded by the special sequences, designated Chi, that stimulate recombination. It has been shown that a Chi sequence can stimulate recombination when RecBCD enters a DNA molecule at the site generated by cutting with *EcoRI*. It seems inevitable that fragmentation of DNA by restriction would reduce the opportunity for recombination to incorporate long stretches of DNA; however, given that DNA ends are recombinogenic, restriction could promote the acquisition of short segments of DNA.

Radman and colleagues have suggested that R–M systems are not required as interspecific barriers to recombination since the DNA sequence differences between *E. coli* and *Salmonella* are sufficient to hinder recombination. It is evident, however, that selection

has maintained a diversity of restriction specificities within one species, and consequently restriction is presumed to play a significant role within a species, in which DNA sequence differences are less likely to affect recombination. Detailed analyses of the effects of restriction on the transfer of DNA between strains of *E. coli* are currently under way and the molecular techniques are available to monitor the sizes and distributions of the DNA fragments transferred between strains.

Kobayashi and colleagues view R–M genes as “selfish” entities on the grounds that loss of the plasmid that encodes them leads to cell death. The experimental evidence for some Type II R–M systems implies that the cells die because residual ENase activity cuts incompletely modified chromosomal DNA. The behavior of Type I systems, on the other hand, is different and is consistent with their ability to diversify sequence specificity; when new specificities are generated by recombination, old ones are readily lost without impairing cell viability.

VII. APPLICATIONS AND COMMERCIAL RELEVANCE

Initially, the opportunity to use enzymes that cut DNA molecules within specific nucleotide sequences added a new dimension to the physical analysis of small genomes. In the early 1970s, maps (restriction maps) could be made in which restriction targets were charted within viral genomes and their mutant derivatives. Within a few years, the same approach was generally applicable to larger genomes. The general extension of molecular methods to eukaryotic genomes depended on the technology that enabled the cloning of DNA fragments, that is, the generation of a population of identical copies of a DNA fragment. In short, DNA from any source could be broken into discrete fragments by restriction ENases, the fragments could be linked together covalently by the enzymatic activity of DNA ligase, and the resulting new combinations of DNA could be amplified following their recovery in *E. coli*. Of course, to achieve amplification of a DNA fragment, and hence a molecular clone, it was necessary to link the DNA fragment to a special DNA molecule capable of autonomous replication in a bacterial cell. This molecule, the vector, may be a plasmid or a virus. Importantly, it is usual for only one recombinant molecule to be amplified within a single bacterial cell. In principle, therefore, one gene can be separated from the many thousands of other genes present in a eukaryotic cell, and this gene can be isolated, amplified, and purified for analysis. The efficiency and power of

molecular cloning have evolved quickly, and the new opportunities have catalyzed the rapid development of associated techniques, most notably those for determining the nucleotide sequences of DNA molecules, the chemical synthesis of DNA, and recently, the extraordinarily efficient amplification of gene sequences *in vitro* by the polymerase chain reaction (PCR). In some cases, amplification *in vitro* obviates the need for amplification *in vivo* since the nucleotide sequence of PCR products can be obtained directly.

The bacterium *E. coli* remains the usual host for the recovery, manipulation, and amplification of recombinant DNA molecules. However, for many of the commonly used experimental organisms the consequence of a mutation can be determined by returning a manipulated gene to the chromosome of the species of origin.

The recombinant DNA technology, including screens based on the detection of DNA by hybridization to a specific probe and the analysis of DNA sequence, is now basic to all fields of biology, biochemistry, and medical research as well as the "biotech industry." Tests dependent on DNA are used to identify contaminants in food, parents of children, persons at the scene of a crime, and the putative position of a specimen in a phylogenetic tree. Mutations in specific genes may be made, their nature confirmed, and their effects monitored. Gene products may be amplified for study and use as experimental or medical reagents. Hormones, cytokines, blood-clotting factors, and vaccines are amongst the medically relevant proteins that have been produced in microorganisms, obviating the need to isolate them from animal tissues.

Most of the enzymes used as reagents in the laboratory are readily available because the genes specifying them have been cloned in vectors designed to increase gene expression. This is true for the ENases used to cut DNA. It is amusing that in the 1980s the generally forgotten, nonclassical, restriction systems identified by Luria and Human (1952) were rediscovered when difficulties were encountered in cloning Type II R-M genes. It was soon appreciated that cloning the genes

for particular MTases was a problem in "wild-type" *E. coli* K-12; the transformed bacteria were killed when modification of their DNA made this DNA a target for the resident M_{cr} restriction systems. Rare survivors were *mcr* mutants, ideal strains for recovering clones of foreign DNA rich in 5mC, as well as genes encoding MTases.

DNA Sequencing and Genomics

Brian A. Dougherty

Bristol-Myers Squibb Pharmaceutical Research Institute

GLOSSARY

bioinformatics Biological informatics, specifically the computer-assisted analysis of genome sequence and experimental data.

DNA microarrays Miniaturized arrays containing thousands of DNA fragments representing genes in an area of a few square centimeters. These “chips” are used mostly to monitor the expression of genomes at the level of messenger RNA.

functional genomics The study of gene function at the genome level.

genomics The study of the genome, or all of the genes in an organism.

proteomics The study of the protein complement, or proteome, of an organism.

whole genome shotgun sequencing A random approach to genome sequencing based on shearing of genomic DNA, followed by cloning, sequencing, and assembly of the entire genome, and ultimately leading to finished, annotated genomic sequence. Sequencing of entire genomes can also be achieved by a sequential shotgun sequencing of a set of overlapping, large insert clones.

Advances in DNA Sequencing, computing, and automation technologies have allowed the sequencing of entire genomes from living organisms. Bacterial genomes range in size from 0.5 to at least 10Mb (1×10^6 base pairs) and are composed of approximately 90% coding regions; therefore,

high-throughput sequencing of randomly cloned DNA fragments represents the most cost-effective way to rapidly obtain genome information for these organisms.

Since the publication in 1995 of the first whole genome sequence for a bacterium, over 60 microbial genome sequences have been published (Table 30.1), and high coverage sequence data have been added to the public domain throughout this period for many other genomes. Sequencing of a microbial genome requires logistical planning for the challenges of high-throughput sequencing, bioinformatic analysis, and presentation of the data in a concise, user-friendly format, usually in the form of a World Wide Web site to supplement a journal publication; this is an intensive process that is often under-appreciated. Following the sequencing, analysis, and initial assignment of function based on similarity to previously identified genes in sequence databases, analysis of gene function at the laboratory bench is required to confirm gene function. These functional genomics studies will also require a substantial scale-up in order to keep up with the high-throughput pace of genome sequencing. Simply stated, in the pre-genomic era genes were usually identified based on a selection for function, followed by the laborious tasks of cloning, subcloning, and sequencing; genome sequencing has reversed this process today, and the challenge of the postgenomic era will be to determine how all the gene products of a genome function, interact, and allow the organism to live.

I. INTRODUCTION: DNA SEQUENCING

DNA sequencing has seen many technological changes during the past two decades, evolving from slab polyacrylamide gels that could resolve 20–50 bp at a time to the 700-bp reads of today. In the late 1970s, DNA sequences were manually read from X-ray film using chemical and enzymatic methods to incorporate radiolabel. During the 1990s fluorescently labeled DNA was resolved on slab gels and read using computerized base-calling programs using sequencers such as the Applied BioSystems 377 model. In the late 1990s, capillary sequencers such as the Amersham MegaBACE and the Applied Biosystems 3700 models were introduced, and dramatically increased the throughput of automated DNA sequencing. The availability of these instruments was the catalyst that allowed the shotgun sequencing of the fruit fly genome, and greatly accelerated the schedule for completion of the Human Genome Project.

Upon publication of the 1.8-Mb chromosome of *Haemophilus influenzae* in 1995, it became apparent to the scientific community that sequencing of bacterial and even eukaryotic genomes was possible by scaling-up existing sequencing technologies. Although the utility of the whole-genome shotgun approach (Fig. 30.1) for sequencing microbial genomes is unquestionable today, the original *H. influenzae* project was in fact deemed an unproven, high-risk venture and was not funded because such a large segment of DNA had not been sequenced by a random approach. The standard paradigm for any large-scale sequencing

projects was based on strategies used for sequencing the human genome and related model organisms. These “top-down” techniques consisted of two phases, an up-front mapping and cosmid-ordering phase, followed by subcloning and sequencing of a minimal tiling path (a complete set of cloned genome fragments with minimal overlap among the cosmids). Sequencing of larger segments of a microbial genome was not attempted due to a computational limitation at that time—existing software packages for the assembly of random DNA fragments were not sufficiently robust to assemble a DNA segment much larger than the size of a cosmid insert (~40 kbp). However, advances based on an unconventional approach to sequencing the human genome set the stage for whole-genome sequencing of smaller genomes. The Venter laboratory at the National Institutes of Health (NIH) and later at The Institute for Genomic Research (TIGR) developed the expressed sequence tag (EST) method for streamlining gene discovery in human genome sequencing by enriching for and sequencing messenger RNAs. By optimizing the conditions for high-throughput fluorescent sequencing and developing the computational software to assemble hundreds of thousands of random sequences into contiguous sequences (contigs), the stage was set to attempt a shotgun approach to sequencing an entire genome, which had last been done for bacteriophage λ in 1977.

The whole genome shotgun sequencing technique is described in the following section, and it consists of four phases: library construction, random sequencing, gap closure, and editing/annotation (Fig. 30.1).

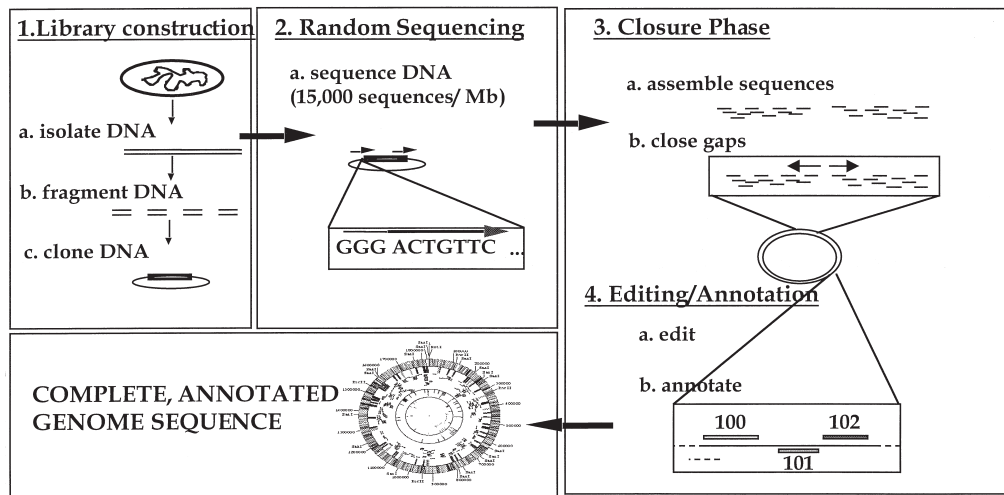

FIGURE 30.1 Strategy for a whole genome random sequencing project.

II. MICROBIAL GENOME SEQUENCING PROJECT

A. Library construction phase

Library construction is the most critical phase of a microbial genome sequencing project. Assuming a completely random library, Lander and Waterman calculated that the sequencing statistics would follow a Poisson distribution (i.e. sequencing enough random reads to add up to one genome equivalent would leave 37% of the genome unsequenced; see Table 30.2). Sequencing of a nonrandom library will result in a significant deviation from the Lander–Waterman model for random sequencing, and the generated assemblies will have too many gaps to be efficiently closed. A library construction procedure has been developed (Fleischmann *et al.*, 1995) to achieve a high order of randomness, and it consists of the following steps:

1. Random shearing of genomic DNA and purification of ~2 kbp fragments.
2. Fragment end repair and ligation to blunt-ended, dephosphorylated vector.
3. Gel purification of the “v + i” (vector plus single insert) band from other forms.
4. Final polishing of free ends and intramolecular ligation of v + i DNA.
5. High-efficiency transformation of *Escherichia coli* strains (DH10B, SURE, etc.).
6. Direct plating onto two-layer antibiotic diffusion plates.

This optimized method results in efficient sequencing because the library is a collection of highly random, single-insert fragments that can be sequenced from both ends using universal primers. Key factors for success include random shearing of the DNA (usually by nebulization), purification of a narrow size range of insert (using minimal amounts of longwave UV light),

TABLE 30.2 Lander–Waterman calculation for random sequencing of a microbial genome (2-Mb size, 500-bp average sequence read length)

No. sequences	% genome sequenced	No. gaps	Average gap size	Fold coverage	Total bp sequenced
4000	63.21	1472	500	1×	2,000,000
8000	86.47	1083	250	2×	4,000,000
12,000	95.02	597	167	3×	6,000,000
16,000	98.17	293	125	4×	8,000,000
20,000	99.33	135	100	5×	10,000,000
24,000	99.75	59	83	6×	12,000,000
28,000	99.91	26	71	7×	14,000,000
32,000	99.97	11	63	8×	16,000,000

a second gel purification of v + i to minimize plasmid clones lacking insert or containing chimeric inserts, propagation of clones in a highly restriction-deficient *E. coli* background, and outgrowth of transformed cells as individual colony-forming units on an antibiotic diffusion plate (rather than standard outgrowth as a mixture of clones in liquid medium, which may select against certain slower growing clones in the transformed population). Even with all these safeguards in place, however, gaps in the genome do occur. This is due to both the statistics of random sequencing and the inability to clone certain DNA fragments, such as those containing strong promoters (e.g. the 16S rRNA promoter in *H. influenzae*) or “toxic” genes (e.g. the complete *HindIII* restriction enzyme gene without the cognate methylase gene present in the transformed *E. coli* strain).

B. Random sequencing phase

After the library is constructed, random sequencing of the individual clones is performed. This involves: (i) the production of tens of thousands of templates in 96-well blocks; (ii) sequencing of the purified plasmid template DNA in both directions; (iii) transfer of the edited sequence reads to a database; and (iv) assembly of the sequence data into contigs.

To ensure that the expected Poisson distribution of random sequences is obtained, the assembled sequence data from the first several thousand sequences are plotted relative to the Lander–Waterman equation (Fig. 30.2). The sequencing and assembly of a verified random library continues until approximately 7- or 8× genome coverage is achieved, which should result in a manageable number of gaps to close (Table 30.2). Based on diminishing return, after sequencing to 7- or 8× random genome coverage with the 2-kbp insert library, directed sequencing strategies are employed for gap closure; for genome sequencing projects in which gap closure will not be pursued, the project goes directly to the annotation phase.

C. Closure phase

Of the three phases of a whole-genome sequencing project discussed so far, this is the most time-consuming; however, closure of a genome results in a complete list of the set of genes. If a certain gene or metabolic pathway is missing from a closed genome, its absence is not due to it being located in an unsequenced gap. Moreover, a complete genome is a linear string of nucleotides, rather than a collection of contiguous sequences of uncertain orientation relative to one

FIGURE 30.2 Plot of Lander–Waterman calculation for random sequencing for a 2-Mb genome with 500-bp average sequence read lengths.

another, and contains genes in linear progression with exact 5' and 3' coordinates.

The forward and reverse reads of the plasmid clones are an important tool used for genome closure. Once the assembled sequences are obtained, any template with a forward sequence read in one assembly and a reverse in the other represents a link between assemblies and is used as a template for primer walking to close the gap. Clone linkage for closure of potentially larger gaps is provided by end sequencing a large insert lambda library and mapping positions of the forward and reverse reads (separated by about 20 kbp) on the assembled contigs.

The previously mentioned gaps are called “sequencing” gaps since a DNA template is available; closure of “physical” gaps is more challenging because no template is immediately available. Depending on the number of gaps to close and tools at one’s disposal, a template is generated for a physical gap by several means, including combinatorial polymerase chain reaction (PCR), screening for large insert clones that span the gap, Southern hybridization fingerprinting, and cycle sequencing using genomic DNA as a template. Once a template is obtained, it is sequenced until the physical gap is closed. The gap closure data are then incorporated into the assembly data, the assembled contigs are joined, and the process is repeated until closure of the entire genome is achieved.

D. Editing and annotation phase

Following genome closure the sequence is edited and annotated. Editing consists of proofreading the sequence and resolving ambiguities or regions of low

coverage by dye terminator sequencing. In addition, possible frameshifts are identified, PCR amplified from genomic DNA, and resequenced. It should be noted, however, that some apparent base insertions, deletions, and frameshifts are authentic. Examples include polymorphisms in repetitive sequences of the *Campylobacter jejuni* genome and more than 20 authentic frameshifts in protein coding regions of the lab-propagated *H. influenzae* Rd organism (several of the counterparts of these genes in other *H. influenzae* strains have been demonstrated to be full-length, functional genes).

Annotation begins with gene finding, which is not an insignificant task in prokaryotes; although stop sites of open reading frames (ORFs) are straightforward, identifying the proper translation initiation codon can be challenging. Annotation also involves characterization of other features of the genome, including repeated nucleotide sequences, gene families, and variations in nucleotide composition. Furthermore, all genes are classified into functional role categories and analyzed as a whole for the presence of various metabolic pathways. In this way, whole-genome sequencing provides a complete picture of the metabolic potential of an organism and lays the groundwork for many follow-up studies once the genetic complement of the cell has been defined.

III. BIOINFORMATICS AND GENOME DATABASES

The need for computational tools to handle genome project data is increasing, and the URLs listed in Table 30.3 represent a fraction of the genomic websites that

continue to proliferate. The genome project monitoring sites given are among the most comprehensive and are continually updated as new genome projects are both initiated and completed. In fact, it is estimated that in addition to the 60-plus microbial genomes completed 7 years after the publication of *Haemophilus* (Table 30.1), hundreds more are in progress. The genome project websites listed provide extensive annotation, role categorization, search capabilities, and genome segment display and retrieval. In the near future, experimental data from functional genomics work (expression of gene under various conditions, phenotype of knockout mutant, protein-protein interaction information, etc.) will be incorporated into these existing structures and provide much added value to the basic research community.

During the course of a genome sequencing project, a variety of tools are required. At the DNA sequencing and assembly stage, software for high-throughput sequencing is needed for automated base calling (e.g. phred and ABI Base Caller) and data tracking/management. An assembly program (e.g. phrap and TIGR Assembler) is then used to find overlaps among the random sequences and build large sets of contiguous sequence. Gaps in the sequence are then closed by directed sequencing; programs to clearly display, track, and update this information are crucial. Gene

finding is then performed using programs that search for ORFs among the assembled sequence data (e.g. Genemark, Critica, and Glimmer) and that use computational techniques to help discriminate the signal of real genes from the noise of potential ORFs found in a microbial genome. The annotation stage involves human inspection of the list of candidate genes and other data to help generate a catalog of genes from the organism (more like a rough draft rather than a final list). Procedures used to determine if a gene is authentic include examining similarity scores, multiple sequence alignments, and published data when similar to that of known genes and examining the sequence for gene-like characteristics (e.g. the presence and proper spacing of a promoter, ribosome binding site, and initiation codon; the presence of a similar gene in the database; the position of the gene in an operon; or nucleotide or codon usage similar to that of the rest of the genome). Functional role category can also be assigned based on similarity to genes of known function, and a picture of the metabolic capacity of the organism emerges. Finally, it should be emphasized that quality annotation is based on bioinformatic analysis beyond assigning the top BLAST similarity score. Motif searches (e.g. Prosite, Blocks, and e-motif) reveal local similarity that may be missed at the global level of a BLAST

search. Also, multiple sequence alignments and phylogenetic relationships between members of a gene family can provide insight into possible function. More detailed analyses are currently providing information about relationships among predicted proteins that may be missed by solely relying on BLAST searches, and gene families are being constructed using hidden Markov modeling (Pfam) and other techniques (e.g. COGs). Finally, molecular modeling comparisons such as threading are being used to gain insight into relationships between proteins seen only at the three-dimensional level.

IV. FUNCTIONAL GENOMICS APPROACHES

A. Comparative genomics

The resources required for a microbial whole-genome sequencing project is not insignificant, with a cost of approximately \$1 million and requiring 1 or 2 years to complete. However, high-throughput sequencing of microbial DNA is the most cost-effective method to obtain genomic information: a typical microbial genome would give several thousand gene sequences at a cost of several hundred dollars per gene (significantly less than the per gene cost of the pregenomic era). This cost is reduced even further by sequencing at a lower average redundancy (3–6× coverage), providing a catalog of the majority of the genes in an organism of interest. These data are sufficient for the purpose of rapidly acquiring a proprietary database of genomic data, often from multiple organisms, and performing functional genomics work with the ultimate goal of producing vaccines or antibiotics. However, the goal of the complete genome project, published in a peer-reviewed journal, is to sequence every base pair of a genome and become a foundation for downstream research by providing a contiguous list of genes, exact 5' and 3' coordinates for each gene, reconstruction of metabolic pathways while accounting for all genes in an organism, and other qualities not available from collections of large contigs.

There are some cases in which genome sequences from two isolates of the same species exist, but often one genome is held as proprietary information (this happens regularly for important microbial pathogens). Genome projects in which data are publicly available for two species of bacteria include those for human pathogens such as *Neisseria meningitidis*, *Helicobacter pylori*, *Staphylococcus aureus*, and *Mycobacterium tuberculosis* to name a few. The latter case will be of special interest because CSU-93 is a highly infectious strain of

M. tuberculosis, and it is possible that “*in silico*” comparisons of the genome sequences relative to the H37Rv strain may point to the mutation(s) or gene(s) responsible for this phenotype. Finally, comparisons by the Blattner laboratory of the completed *E. coli* K-12 strain to the enterohemorrhagic *E. coli* O157:H7 have provided some interesting findings. Although conventional wisdom would have suggested that the pathogenic O157 was a K-12 backbone plus some large segments of additional DNA, such as the 92-kb virulence plasmid or the 43-kb LEE pathogenicity island, it was determined from shotgun sequencing that the O157 genome is actually a fine mosaic of O157 and K-12 DNA and includes 1.2Mb of DNA unique to O157 while lacking ~0.15Mb of DNA known to be unique to the completed K-12 genome. These results provide a glimpse into the importance of comparative genomics work and the complex ways in which genomes/microbes evolve and adapt.

B. RNA-level differential gene expression

Researchers are interested in differential gene expression; that is, what genes are up- and down-regulated under a specific set of conditions (wild-type versus isogenic mutant, growth with and without an antibiotic present, and growth in the lab versus in a host for pathogens). Prior to genome sequences being widely available, differential display PCR was used to identify differentially expressed genes. Random primers are used for reverse transcription of message followed by amplification and agarose electrophoresis. Differentially labeled bands are isolated, cloned, and sequenced to determine the expressed genes. With eukarotic cells, quantitative EST sequencing or serial analysis of gene expression (SAGE) can also be used for differential gene expression without *a priori* knowledge of genome sequences, but the density of genes in bacteria coupled with the inability to apply mRNA-enrichment procedures based on polyadenylation has limited the use of these techniques in bacteria.

Molecular techniques previously used to study a single gene are now being applied to entire genomes. In RNA-level gene expression, researchers have applied DNA-blot hybridization and RT-PCR techniques to monitor the expression of thousands of genes at once. DNA microarrays can be thought of as high-throughput dot blots using DNA on a solid “chip” surface to report expression patterns for thousands of genes. Several different microarraying technologies are being used, and although costs continue to decrease the equipment is currently beyond the reach of the average lab. For synthetic arrays, such as the Affymetrix chip (<http://www.affymetrix.com>),

photolithographic techniques are used to synthesize oligonucleotides on a 1.2-cm² silicon chip (hundreds of thousands of addressable positions per chip). For spotted arrays, such as those made by Stanford University (<http://cmgm.stanford.edu/pbrown>) or Molecular Dynamics (<http://www.mdyn.com>), an *x-y-z*-stage robot is used to deposit DNA spots, (usually PCR products but also ~70 base oligonucleotides), onto a treated glass microscope slide. In either case, DNA representing thousands of genes are linked to a solid surface, then hybridized with fluorescently labeled RNA from different conditions, followed by scanning to quantitate hybridized probe. In the case of spotted arrays, the use of different fluorescent dyes for each experimental condition allows for greater sensitivity and simultaneous hybridization of two or more samples on the same chip. Thus, expression data from thousands of genes (even entire genomes in the case of microbes) are then deconvoluted and analyzed.

C. Protein-level differential gene expression

Just as gene expression can be monitored at the transcription level, it can also be measured at the translation level by analyzing the entire protein complement of the genome, or proteome. At the core of these proteomics experiments is a separation technology that was developed more than two decades ago—two-dimensional polyacrylamide gel electrophoresis (2D-PAGE). Today, however, a new generation of instruments using mass spectroscopy (MS; <http://www.asms.org>) techniques afford highly accurate mass determination, giving a rapid, high-throughput path from a spot on a 2D-PAGE gel to an identified protein. Translation of whole-genome DNA sequence data gives the theoretical mass and isoelectric point for all protein gene products, and studies indicate that proteins identified from 2D-PAGE gels by electrospray MS or amino acid sequencing techniques correlate closely to these theoretical values (although approximately 20% of the spots represent isoforms, which are protein modifications that alter predicted migration positions of proteins). Variations on these techniques are being used, such as matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) and surface-enhanced laser desorption/ionization (SELDI). The SELDI technique is an interesting twist on chip technology, giving a “protein chip” (CIPHERGEN, <http://www.ciphergen.com>) capable of on-chip protein enrichment and real-time estimates of protein mass.

One question that needs to be resolved in the postgenomic era is whether differential gene expression is best measured at the RNA or protein level; it is most likely, however, that researchers doing whole-genome

expression studies will want to use both microarraying and proteomics technologies to assess gene expression levels.

D. Mutagenesis

With microbes, one of the classic methods for determining gene function is via mutagenesis. For many large-scale studies, transposons or antibiotic cassettes are used to disrupt genes, providing an isogenic pair of strains, a wild type, and a null mutant. By sequencing out from transposon or cassette, one can determine a “genome sequence tag” for the disrupted gene. In the pregenomic era, identification of the entire gene and surrounding genes/operons would have involved a substantial effort of cloning and sequencing, but because of the availability of genomic sequence data, the tag and sequence data allow one to rapidly map large numbers of mutants. The recent development of *in vitro* transposition systems has simplified the transposon-hopping step to a microfuge tube reaction and has great potential for use with naturally transformable organisms. Genome footprinting is another technique based on saturation mutagenesis that allows PCR-based scanning of a whole genome for gene essentiality under different experimental conditions. Finally, rather than being restricted to a random approach for mutagenesis, the availability of genome sequence data allows the directed knockout of genes in genetically amenable systems, and publicly announced programs to knockout every gene in the genome are proceeding for *Bacillus subtilis* (<http://locus.jouy.inra.fr/cgi-bin/genmic/madbase/progs/madbase.operl>) and *Saccharomyces cerevisiae* (http://sequence-www.stanford.edu/group/yeast_deletion_project/deletions3.html).

One advance that is invaluable for studies involving pools of mutants is oligonucleotide tag (or “barcode”) mutagenesis. In this technique, a unique oligonucleotide tag is included in the transposon/cassette and then introduced into each mutant. In the case of “signature-tagged mutagenesis” of pathogenic bacteria, pools of 96 bar-coded mutants are used to infect a host organism, the bacteria are collected, the DNA are isolated, and the bar code is amplified and then hybridized to a 96-spot array of DNA from each mutant. By comparing hybridization of the bar-code tag from *in vivo*-grown pools of mutants with that from *in vitro*-grown mutants, one can identify those mutants less successful at causing infection in a host—potential new virulence factors. Infection of mammals, as opposed to growing mutants in laboratory media, is a much more realistic environment for learning about microbial pathogenesis, and the bar-coding procedure

has been very useful because it minimizes the number of experimental animals needed for infection. The whole-genome knockout program for *S. cerevisiae* incorporates bar codes into the cassettes, and preliminary experiments for monitoring pools of mutants have successfully employed microarray chips for the DNA–DNA hybridization step. Thus, the use of DNA microarrays for parallel processing of both mutant growth rates and global transcription patterns has enormous implications for changing molecular microbiology.

E. Other functional studies

Numerous functional studies in addition to those mentioned previously are being performed for sequenced bacteria. This list is not inclusive, and it should again be mentioned that the most well-coordinated functional analysis programs currently being performed are those for *B. subtilis* and *S. cerevisiae*. Methods currently being used include: (i) reporter fusion analyses, constructed for entire genomes, to provide gene expression data using whole cells; (ii) protein–protein interactions to determine what proteins interact with each other in a cell are providing important information to be used in conjunction with gene function studies; (iii) protein overexpression, using a high-throughput, brute-force protein overexpression methodology involving designing primers to the 5' and 3' ends of sequenced genes, cloning into T7 polymerase-driven vectors with affinity tags, and expressing and purifying the gene products using *E. coli*, with purified protein being used for numerous applications including *in vitro* screening for novel inhibitors, use as a component for vaccines, and for determining the three-dimensional structure of the expressed protein; (iv) structural genomics—in addition to modeling the theoretical structures of all the predicted proteins in a genome, determining the actual structure of expressed proteins of interest is a focal point for structural genomics, for use in rational drug design and for adding to the accumulating structure databases and helping to refine predictive programs; and (v) metabolic reconstruction studies, with initial efforts focusing on the well-studied *E. coli*, are being used as a framework for other microbes. Complete sequence data and excellent annotation are critical for all of these types of studies.

The trend for functional analysis work is increased throughput, which usually implies both miniaturization and automation. Besides the microarrays mentioned previously, miniaturization technology is progressing to the point of “lab-on-a-chip” design. These nanoreactors are capable of performing routine molecular biological techniques in tandem; for

example, add a sample to the nanoreactor and DNA is extracted, purified, and separated by size for such applications as Southern hybridization or nucleotide sequencing. Automation is also apparent in any high-throughput sequencing lab, which incorporates robots for every step possible, including clone picking and arraying, plasmid purification, and numerous pipeting and reaction steps. Clearly, the automation that has provided an explosion of genome sequences will be applied to functional studies so that laboratory experimentation can keep pace with the high-throughput of genome sequencing.

V. CONCLUSIONS

The applications of high-throughput sequencing and computational methods that led to the first whole genome sequence for a living organism is revolutionizing microbiology. The present golden era of genome sequencing will soon lead to a challenging postgenomic era, in which laboratory experiments must be designed in order to determine how the thousands of genes in each microbe's genome function, interact, and allow these organisms to survive and evolve. To meet this challenge, researchers will become even more dependent on automation and computers to allow them to continually push the limits of what is achievable in genomic sequencing and functional genomics.

GLOSSARY

biofilm Matrix-enclosed bacterial populations adherent to each other and/or to surfaces or interfaces.

cell sorter An instrument that uses optical or mechanical technologies which allow the separation of cells on the basis of size or cellular properties.

chemotaxis A movement response by microorganisms in which the stimulus is a chemical concentration gradient.

community An assemblage of populations of microorganisms which occur and interact within a given habitat.

ecosystem In terms of microorganisms, the totality of biotic and abiotic interactions to which the organism is exposed.

food web The interaction of communities of organisms with varying functional capabilities.

habitat A location where microorganisms occur.

interspecies hydrogen transfer The coupling or syntrophic relationship of hydrogen producers and hydrogen consumers.

Koch's postulates A concept embodied in these postulates defines the fundamental questions needed to address the function of a microbial population within a given habitat or its role in a function.

laser scanning confocal microscope An approach to microscopy which uses intense laser light beams, optics which exclude light from parts other than the specimen, and computer-assisted image enhancement

to provide a nearly three-dimensional image without sample destruction or fixation.

microelectrode A micro version of pH, O₂, and specific ion electrodes which allow the exploration of microhabitats.

PCR Polymerase chain reaction; a method for increasing the number of copies of a target nucleic-acid sequence without having to culture the organism.

phylloplane The aboveground exposed surfaces of plants that are available for the colonization of microorganisms.

population A group of individuals of one species within a defined area or space.

probe A chemical or molecular technique which allows the detection or quantitation of a population or activity of microorganisms.

rhizosphere The region of soil which adheres to plant roots or is influenced by the activities of plant roots.

rumen A chamber anterior to the digestive tract of animals which harbors microorganisms that metabolize ingesta and provide metabolic intermediates to the animal, which serve as energy and biochemical precursors.

syntrophic An interpopulation interaction that involves two or more populations which provide nutritional requirements for each other.

Microorganisms are often considered to be among the first life forms on earth. Fascination with these beings was initially predisposed to their small size and simple forms. Early

observations of microorganisms (in the seventeenth century) by Leeuwenhoek, with the aid of the first microscope, were followed by the demonstration of the role of microorganisms in the process of fermentation and spoilage by Pasteur and, eventually, the development of a means to prevent the growth of microorganisms, that is, pasteurization.

I. EVOLUTION OF MICROBIAL ECOLOGY AS A DISCIPLINE

Isolation of causative microorganisms of disease, as well as pure culture techniques, evolved in the late 1800s; Koch's postulates provided a solid basis for studying microorganisms and their roles. The era that followed provided for the continued isolation of microorganisms, the definition of their metabolic capabilities, and, in turn, their implied roles in important biogeochemical processes, that is, in the nitrogen and sulfur cycle. Attention was given to organisms from specific habitats, that is, soil, water, animal, and plants. The findings demonstrated the vast numbers of diverse microbiological forms and functions found in nearly every location that was sampled. Eventually, microbiological subdisciplines dealing with microbial associations of natural (soil, water) and manmade (food, industrial, and other) environments were established.

Within the last 30 years, it has been recognized that common microorganisms are observed in many habitats and common principles are involved in the mechanisms describing the associations of those microbes in varying habitats. The observation that individual populations of microorganisms are rarely found alone suggests potential interactions between populations and with their surrounding physicochemical environments. Additionally, the observation that they associate or align themselves within specific "strata" or gradients of physiochemical parameters points to the large number of metabolic functions of these organisms. They also have been shown to have the ability to sense (e.g. chemotaxis) and move by various means of locomotion within these gradients to maintain selected conditions for their growth.

The field of ecology is defined as a discipline of biology which deals with organisms' interactions with each other and surrounding environments. As one might expect, these aforementioned observations of microorganisms and their habitats led to the development of the subdiscipline known as microbial ecology. This development further emphasizes the need to establish a union between the examinations of the physicochemical nature of a habitat and microbiological investigations. An equally important emphasis in

microbial ecology is the structure and activities associated with microbial communities rather than the earlier emphasis in causative populations of disease or specific processes.

II. MICROBIAL COMMUNITIES

Although observations of microorganisms and their associations have been made in numerous habitats, a few of these observations are felt to highlight the importance of the interactions between microorganisms which leads to community versus population responses.

The rumen ecosystem has received considerable attention, which has been driven principally by economic considerations. Research in this system has, however, defined the syntrophic relationship between members of the microbial fermentative community and the animal's growth and survival. Technically, approaches to this ecological niche present somewhat greater difficulties than those of soil or natural waters. The ecosystem is internal to the animal and the microbes are strict anaerobes. Mechanistically, however, rumen microbial ecology is relatively easier to discern, inasmuch as both input and output to and from the system are clearly defined, in much a similar relationship as an industrial bioreactor. It is interesting to note that syntrophic community-level interactions are frequently illustrated with the rumen system, in regard to hydrogen transfer and methane production.

The classic anaerobic food web first described by Hungate, and later by Wolf, which occurs in the rumen, involves the interpopulation interactions among bacterial communities capable of plant polysaccharide hydrolysis (e.g. cellulose), monomer fermenting communities, fatty acid-oxidizing communities, and, finally, terminal communities (e.g. methanogenesis), which oxidize fatty acids and reduce CO_2 to CH_4 . The hydrogen is derived from previous oxidative steps. The coupling, or syntrophic, relationship between hydrogen producers and hydrogen consumers (interspecies hydrogen transfer) is now recognized as a fundamental relationship in other systems dominated by anaerobic microorganisms. In the rumen, rates and extent of metabolism are controlled by the interdependence of one community on another. The rumen system has also served as an example of a strategy for, an approach to, and methods to conduct similar investigations of animal-microbe associations, be it the crop of tropical birds or the intestinal tract of termites. Similar interactions have been observed in other anaerobic systems (such as sewage sludge, lake and marine sediments), which suggest common

controls and mechanisms associated with metabolism of complex organic compounds in all of these systems. These relationships have also been shown to be involved in the metabolism of naturally occurring and manmade halogenated compounds. One such reaction involved dehalogenation by replacement of a halogen substituent of a molecule with a hydrogen atom. The hydrogen is derived from hydrogen-producing fermentative microorganisms.

Questions related to the response of these communities and the interactions among populations to disturbance of their physical-chemical environment will rely on tools which allow analyses of change in both the nature of the populations involved and changes in their functions. Do populations adapt and respond phenotypically or do they replace each other?

Traditional food web descriptions in aquatic and terrestrial ecosystems have often failed to consider the role of microbial interactions as a contribution to carbon and nitrogen cycling in these systems. Early recognition of these contributions was blurred by the examination of individual populations of organisms and by inadequately examining the interactions and controls of population size and distribution in the surrounding communities. Figure 31.1 illustrates, in its simplest form, the relationship among primary producers in aquatic/marine or terrestrial environments, heterotrophic bacteria, and phagotrophic protozoans or zooplankton.

Primary producers release soluble organic compounds (root exudates, algal metabolites), which are consumed by heterotrophic bacteria, which are subsequently grazed by phagotrophic protozoans or zooplankton. The grazers excrete nitrogen and phosphorus, which is used by the primary producers.

In sum, these observations have strikingly modified the contemporary view of the structure and mechanistic controls and regulation of growth of higher plant and animal forms in aquatic and terrestrial systems. They also point to the importance of a

thorough understanding of these interactions if one is to consider management of these associations in applied applications, for example, sustainable agriculture or aquaculture.

Microbial biofilm communities were first described by Zobell and Anderson. Over the past two decades, their significance and ubiquity have been documented. It is now recognized that biofilm communities predominate numerically and metabolically in most ecosystems. Further, it is clear that biofilm cells are fundamentally phenotypically distinct from non-adhering cells. It now appears that the ability to form surface-associated structured biofilms is a common characteristic of, at least, bacteria. Remarkable intercellular and interspecies interactions, facilitated by chemicals released by these organisms, leads to complex structured communities, made up of both prokaryotic and eukaryotic organisms.

These examples, however, primarily involve interactions based on an exchange of chemical metabolites. The fact that these described interactions involve high densities of cells in close proximity to each other, for example, biofilm, can also lead to intercellular exchange of genetic information, which can lead to adaptive change in function within communities. Knowledge of naturally occurring phenotypic and genotypic viability of microorganisms has been hampered because the majority of our knowledge comes from laboratory-selected strains, grown under controlled conditions, and on a medium which has no resemblance to the environment from which they were selected. It is important to realize that approaches to microbial ecology must recognize not only isolated individual populations but, more directly, the interactions of populations within a community and the resultant effect on the overall functions of the community.

III. APPROACHES TO MICROBIAL ECOLOGY

The fundamental approach to higher plant and animal ecological studies uses quantitative observations of specific populations in various environments. For over 100 years, plant and animal ecologists have observed and detailed the frequency of occurrence of specific plant and animal populations under various environmental conditions. These observations have led to the development of models for predicting the occurrence of, as well as relationship between, the organisms and the associated environments in which they were observed. Recently, these observations have been complemented with physiological and genetic

FIGURE 31.1 Relationship of primary producers, heterotrophic bacteria, and bacterial consumers in aquatic/marine and terrestrial environments.

approaches that suggest specific mechanisms of selection which have led to the observed frequency or distribution of organisms. Unfortunately, our understanding of microbial systems is still embryonic in both description and prediction.

Kluyver and van Neil, in 1956, estimated that about one half the "living protoplasm" on earth is microbial. This estimate is now considered conservative, and the sheer numbers represent a daunting challenge to the microbial ecologist. Even the most modern techniques do not allow routine quantification of microbial numbers and definition of specific populations. It is principally the size of the microorganism, and, equally important, the size of the local habitat, that creates a considerable constraint on the observation of microorganisms in natural surroundings. Numbers of organisms ranging from 1 million cells per milliliter of water to 10 billion cells per gram of human fecal material. Further, the spatial distribution of these organisms within these habitats makes it difficult to recover a representative sample to examine. *In situ* observations are further complicated by our inability to observe this environment without disturbing the microorganism's natural habitat. The various surfaces and potential differences in chemistries of the habitat provide varying degrees of carbon and nitrogen resources and physicochemical environments (e.g. gaseous exchange) for colonizing microorganisms. Additionally, other organisms, micro- and macro-alike, have a potential impact on the native organisms. Grazing of microorganisms by other microbes or faunal components of a habitat have a significant impact on the numbers and types of microorganisms present.

As noted, microbial ecology evolved as a cross-discipline of standard microbiology and environmental analytical analysis. The activity of a specific population or community of microorganisms was inferred by estimating their relative numbers by direct microscope counts, viable colonial or turbidimetric determinations, or specific chemical analyses (e.g. chlorophyll for algae). Unfortunately, limitations by both the microbial and the environmental analyses have, in most cases, failed to accurately define the ecology of microbial habitats. Recently, novel analytical and microbiological methodologies have provided tools for expanding our view of microbial habitats, in a fashion that is neither constrained by the microscale of the environment, nor limited by our ability to selectively cultivate members of a community.

In situ observation of microorganisms has been expanded through use of laser confocal microscopy, an advancement which provides for a kind of "X-ray" imaging of material requiring neither disturbance nor

fixation. Similarly, laser optical trapping allows the removal of individual cells from a habitat. These techniques provide new insights to our understanding of population components of communities. These increases in optical resolution also provide a means of sorting communities either by size or chemical factors through the use of cell sorters.

Advancements have also been made in developing methodology to simulate the microhabitats and physicochemical gradients which occur therein. It is interesting to note that one of the pioneering environmental microbiologists, Winogradsky simulated gradients of light, water, sulfide, and oxygen to describe relationships between sulfide-oxidizing photo-autotrophic bacteria, sulfate-reducing, and chemoautotrophic sulfur-oxidizing organisms in his Winogradsky column. Advances using gels and gradostats to simulate diffusion barriers allow us to expand our knowledge concerning relationships between the spatial heterogeneity of the physicochemical environment and the distribution of diverse groups of microorganisms. Combined with microelectrode techniques, precise analytical measurements will complement these microbial investigations. Although our abilities to observe organisms and to better understand the physical and chemical nature of their habits have improved, we still are unable to isolate a high percentage of these observable organisms. Nevertheless, within the last 30 years, the number of previously undescribed microorganisms has increased significantly.

In an effort to forego the inherent problems of the microscopic and numerical diversity of the microbial world, recent method development has approached the microbial component of the unseen habitats at the macromolecular level. The recognition that diversity is intrinsically related to the organism's genetics has provided a sound basis for separation and characterization of both microscopic and macroscopic life.

Examination of the heterogeneity of DNA in soil suggests that as many as 10,000 bacterial species can be harbored in 100 g of soil. This estimate only includes the bacterial fraction and, again, reinforces the challenge presented to understanding the diversity of microorganisms in natural systems. From an ecological perspective, it also presents a challenge to understanding how so many species coexist in such small areas.

Recombinant DNA technology has allowed the identification and determination of the specific nucleotide sequence of genes. It has provided ecologists with novel methods to pursue community structure. In practice, microbial community samples can be analyzed without cultivation or microscopic observation of microorganisms. In brief, nucleic acid is isolated from the sample and utilized for hybridization studies

with the corresponding gene of interest (i.e. the probe). This probe can represent either a metabolic gene or a systematic determinant, such as the 16S rRNA gene sequence. In turn, as one may infer, the sample can be evaluated in terms of population diversity at the species level or community diversity at the kingdom level (Eukaryotic versus Prokaryotic). All of these analyses have been expanded by inclusion of the polymerase chain reaction (PCR), a method allowing amplification and subsequent detection of as few as 10 microorganisms. Interestingly, these methods have, in fact, relied on previous isolation and characterization of specific microbial populations prior to isolation of a gene for use as a probe. These investigations have, however, illustrated the universal nature of certain sequences, such as from 16S rRNA genes, for random use in community analyses. An example of this technology is the use of various profiling techniques. Separate PCR-amplified 16S rRNA gene-fragment sequences are separated, and the resulting numbers provide an estimate of diversity within the community.

Areas that still remain to be explored in microbial ecology are the relationship of microbial diversity to the response of microbial communities to varying degrees of disturbance and the relationship between diversity and the function of the community. In higher plant and animal systems, the relationship of diversity within communities to their resistance to change or recovery after disturbance (e.g. fire, tillage) has been discussed and debated for decades. Various indices have been used to calculate diversity within communities. In their simplest form, these indices represent the number of species found within the community; therefore, communities with many species are described as having high diversity. Other indices relate the dominance of specific species to the total diversity, such that even communities with high diversity can have a few populations which dominate activity within the community. Our current inability to adequately isolate all microorganisms and the lack of distinctive morphological characteristics fail to provide us with accurate methods for measuring indices of diversity. Continued improvements in our analytical skills in identifying the macromolecular characteristics of microorganisms will provide a basis for estimating diversity at the phylogenetic level.

Profiles of cellular or phospholipid fatty acids from lipids extracted from communities or specific chemical or antigenic determinants may provide a snapshot of changes within microbial communities after disturbance. Community-level assays of the functional diversity of populations based on carbon source utilization also provide indications of changes following disturbance.

IV. FUTURE DIRECTIONS IN MICROBIAL ECOLOGY

It has often been said that advancements in microbial ecology are limited by the methods which are available to analyze microbial systems. Some of the advances made in the analytical and molecular methods over the past decade have been illustrated in this overview. Although continued advancements in the use of microelectrodes and optical methods increase our abilities to measure and observe microorganisms emphasis must increase on the refinement of techniques to discern changes in microbial community structure and the impact of these changes on the function of the community. A significant area of contemporary concern is the remediation of habitats contaminated with anthropogenic sources of organic and inorganic compounds.

The applied area of bioremediation is, and will continue to be, a timely subject in the decades to come. The use and management of the intrinsic properties of microbial communities will provide stimulus for applied microbial ecology. Although this area is yet to be accurately defined, in principle, the directive is to promote microbial dissimilation of anthropogenic compounds in a controlled manner.

In a similar manner, a reduced input of anthropogenic chemicals in agricultural systems to reduce environmental contamination will result in greater reliance on activities of the soil microbial communities.

These and other applications require further understanding of the structure and activities of microbial communities. Also required is an understanding of changes in the structure and function of these communities in relation to changes in the physiochemical environments associated with them. This, in fact, is microbial ecology.

Emerging infections

David L. Heymann

World Health Organization

GLOSSARY

amplification of transmission The increased spread of infectious disease that occurs naturally or because of facilitating factors, such as nonsterilized needles and syringes, that can result in an increase in transmission of infections such as hepatitis.

anti-infective (drug) resistance The ability of a virus, bacterium, or parasite to defend itself against a drug that was previously effective. Drug resistance is occurring for bacterial infections such as tuberculosis and gonorrhoea, for parasitic infections such as malaria, and for the human immunodeficiency virus (HIV).

eradication The complete interruption of transmission of an infectious disease and the disappearance of the virus, bacterium, or parasite that caused that infection. The only infectious disease that has been eradicated is smallpox, which was declared eradicated in 1980.

International Health Regulations Principles for protection against infectious diseases aimed at ensuring maximum security against the international spread of infectious disease. The Regulations provide public health norms and standards for air- and seaports to prevent the entry of infectious diseases, and require reporting to the World Health Organization (WHO) the occurrence of three infectious diseases: cholera, plague, and yellow fever.

re-emerging infection A known infectious disease that had fallen to such low prevalence or incidence that it was no longer considered a public health problem, but that is presently increasing in prevalence or incidence. Re-emerging infections include tuberculosis, which has increased worldwide since the early 1980s, dengue in tropical regions, and diphtheria in eastern Europe.

Emerging Infections are newly identified and previously unknown infectious diseases. Since 1970 there have been over 30 emerging infections identified, causing diseases ranging from diarrheal disease among children, hepatitis, and AIDS to Ebola hemorrhagic fever.

I. A 25-YEAR PERSPECTIVE

In the Democratic Republic of the Congo (DRC, formerly Zaire), the decrease in smallpox vaccination coverage, poverty, and civil unrest causing humans to penetrate deep into the tropical rain forest in search of food may have resulted in breaches in the species barrier between humans and animals, causing an extended and continuing outbreak of human monkeypox. During the 1970s and 1980s, when this zoonotic disease was the subject of extensive studies, it was shown that the monkeypox virus infected humans, but that person-to-person transmission beyond three generations was rare. The outbreak of

TABLE 32.1 Principal newly identified infectious organisms associated with diseases^a

Year	Newly identified organism	Disease (year and place of first recognized or documented case)
<i>Diseases primarily transmitted by food and drinking water</i>		
1973	Rotavirus	Infantile diarrhea
1974	Parvovirus B19	Fifth disease
1976	<i>Cryptosporidium parvum</i>	Acute enterocolitis
1977	<i>Campylobacter jejuni</i>	Campylobacter enteritis
1982	<i>Escherichia coli</i> 0157:H7	Haemorrhagic colitis with haemolytic uremic syndrome
1983	<i>Helicobacter pylori</i>	Gastric ulcers
1986	<i>Cyclospora cayatanensis</i>	Persistent diarrhoea
1989	Hepatitis E virus	Enterically transmitted non-A and non-B hepatitis (1979, India)
1992	<i>Vibrio cholerae</i> 0139	New strain of epidemic cholera (1992, India)
<i>Unclear modes of transmission, thought to be primarily transmitted by drinking water</i>		
1985	<i>Enterocytozoon bienewisi</i>	Diarrhea
1991	<i>Encephalitozoon hellem</i>	Systemic disease with conjunctivitis, in AIDS patients
1993	<i>Encephalitozoon cuniculi</i>	Parasitic disseminated disease, seizures (1959, Japan)
1993	<i>Septata intestinalis</i>	Persistent diarrhea in AIDS patients
<i>Diseases primarily transmitted by close contact with infectious individuals, excluding sexually transmitted diseases, nosocomial infections and viral haemorrhagic fevers</i>		
1980	HTLV-1	T-cell lymphoma leukemia
1982	HTLV II	Hairy cell leukemia
1988	HHV-6	Rosela subitum
1993	<i>Influenza A/Beijing/32 virus</i>	Influenza
1995	HHV-8	Associated with Kaposi sarcoma in AIDS patients
1995	<i>Influenza A/Wuhan/359/95 virus</i>	Influenza
2003	SARS coronavirus	Severe acute respiratory syndrome
<i>Sexually transmitted diseases</i>		
1983	HIV-1	AIDS (1981)
1986	HIV-2	Less pathogenic than HIV-1 infection
<i>Nosocomial and related infections</i>		
1981	Staphylococcus toxin	Toxic shock syndrome
1988	Hepatitis C	Parenterally transmitted non-A non-B hepatitis
1995	Hepatitis G viruses	Parenterally transmitted non-A non-B hepatitis
<i>Human zoonoses and vector-borne diseases, including viral haemorrhagic fevers, transmitted by close contact with animals or animal products, excluding food-borne diseases</i>		
1977	Hantaan virus	Hemorrhagic fever with renal syndrome (1951)
1990	Reston strain of Ebola virus	Human infection documented but without symptoms (1990)
1991	Guanarito virus	Venezuelan hemorrhagic fever (1989)
1992	<i>Bartonella henselae</i>	Cat-scratch disease (1950s)
1993	Sin nombre virus	Hantavirus pulmonary syndrome (1993)
1994	Sabiä virus	Brazilian hemorrhagic fever (1955)
1997	<i>Influenza A (H5N1)</i>	Avian influenza
1998	Nipah virus	Severe encephalitis
<i>Tick-borne</i>		
1982	<i>Borrelia burgdorferi</i>	Lyme disease (1975)
1989	<i>Ehrlichia chaffeensis</i>	Human ehrlichiosis
1991	New species of <i>Babesia</i>	Atypical babesiosis
<i>Unknown animal vector</i>		
1977	Ebola virus	Ebola hemorrhagic fever (1976, Zaire and Sudan)
1994	Ebola virus, Ivory Coast strain	Ebola hemorrhagic fever
<i>Soil-borne diseases, airborne diseases and diseases associated with recreational water with no evidence of direct person-to-person transmission</i>		
1976	<i>Legionella pneumophila</i>	Legionellosis (1947)

^aFrom G. Rodier, WHO.

human monkeypox in 1996–1997, and continuing intermittently since then, is a clear example of the ability of infectious diseases to exploit weaknesses in our defenses against them.

Numerous infectious diseases have found weakened entry points into human populations and emerged or re-emerged since the 1970s (see Table 32.1). In the early to mid 1970s, for example, classic dengue fever had just begun to reappear in Latin America after it had been almost eliminated as a result of mosquito control efforts in the 1950s and 1960s. Today, dengue is hyper-endemic in most of Latin America. In 2001 alone, Latin America reported over 609,000 cases of dengue, of which 15,000 were of the hemorrhagic form. These figures represent more than a doubling of cases reported for the same region in 1995. Outbreaks are also becoming more explosive. An outbreak in Brazil in 2002 caused over 500,000 cases in one of the largest outbreaks ever recorded. A pandemic in 1998, in which 1.2 million cases of dengue fever and dengue haemorrhagic fever were reported from 56 countries, was unprecedented. In 1991, cholera, which had not been reported in Latin America for over 100 years, re-emerged in Peru with over 320,000 cases and nearly 3000 deaths, and rapidly spread throughout the continent to cause well over 1 million cases in a continuing and widespread epidemic.

In North America, *Legionella* infection was first identified in 1976 in an outbreak among war veterans attending a conference in Philadelphia (US). Legionellosis is now known to occur worldwide and poses a threat to travellers exposed to poorly maintained air conditioning systems. In the Netherlands, in 1999, an outbreak of legionellosis occurred which was subsequently traced to whirlpool baths exhibited at a flower show visited by 80,000 people. Local cooling towers are considered the likely source of a large outbreak of legionellosis, involving 751 cases and two deaths, that occurred in Spain in 2001.

During this same 25-year period, a new disease in cattle, bovine spongiform encephalopathy, was identified in the United Kingdom in 1986 and, by 2002, had spread to 19 additional countries around the world. The disease is associated with the appearance in 1996 of a previously unknown variant of the invariably fatal Creutzfeldt–Jakob disease that had occurred in over 100 persons by the beginning of 2002. Within a decade, food-borne infection by *E. coli* O157, unknown in the 1970s, had become a food-safety concern in Japan, Europe, and in the Americas. Hepatitis C was first identified in 1989 and is now thought to be present in at least 3% of the world's population, while hepatitis B has reached levels exceeding 90% in populations at high risk from the tropics to eastern Europe.

Tuberculosis, including multidrug-resistant forms, took advantage of weakened infrastructures in the countries of the former Soviet Union and re-emerged, with cases more than doubling in less than 7 years and with over 20% of patients in prison settings infected with multidrug-resistant strains in 2001. In the Hong Kong Special Administrative Region of China, 18 cases of human infection with influenza A virus sub-type H5N1, previously confined to birds, occurred in 1997, causing six deaths and raising considerable alarm. Human African trypanosomiasis, which had been virtually eliminated in the 1960s, resurged in an epidemic that is currently thought to infect from 300,000 to 500,000 people.

In 1976, the Ebola virus was identified for the first time as causing a disease that has come to symbolize emerging diseases and their potential impact on populations without previous immunological experience. The largest recorded outbreak, which began in Uganda in 2001, caused 425 confirmed cases and 224 deaths. Altogether, Ebola has caused just under 2000 cases and around 1250 deaths since its identification in simultaneous outbreaks in Zaire and Sudan. In 1976, at the time of the first Ebola outbreak in Zaire, HIV seroprevalence was already almost 1% in some rural parts of Zaire, as shown retrospectively in blood that had been drawn from persons living in communities around the site of the 1976 outbreak, and HIV has since become a pre-occupying problem in public health worldwide.

II. MISPLACED OPTIMISM

In this same 25-year period the eradication of smallpox was achieved. This unparalleled public health accomplishment resulted in immeasurable savings in human suffering, death, and money, and stimulated other eradication initiatives. However, recent concerns about the possible deliberate use of variola virus as a biological weapon prompted some countries to consider introduction of population-wide pre-emptive vaccination, but after close deliberation WHO recommendations of October 2001 were accepted by most countries. The WHO is currently leading international initiatives to eradicate poliomyelitis and dracunculiasis and to eliminate African trypanosomiasis, Chagas disease, leprosy, lymphatic filariasis, onchocerciasis, and blinding trachoma. Since the global polio eradication initiative was launched in 1988, three regions have been certified as free of the disease: the Americas in 1994, the Western Pacific in 2000, and Europe in 2002. Reported cases of polio have dropped from an estimated 350,000 cases in 125

countries in 1988 to 480 cases reported to WHO in 2001 from 10 endemic countries. Reported cases of dracunculiasis have decreased from over 900,000 in 1989 to less than 64,000 in 2001, with the majority of cases in one endemic country. Of the several diseases targeted for elimination, goals have been reached for the original onchocerciasis programme in West Africa and for leprosy, where global elimination was declared in 2001. Chagas disease, likewise, continues its downward trend towards elimination.

The eradication of smallpox boosted an already growing optimism that infectious diseases were no longer a threat, at least to industrialized countries. This optimism had prevailed in many industrialized countries since the 1950s, a period that saw an unprecedented development of new vaccines and antimicrobial agents and encouraged a transfer of resources and public health specialists away from infectious disease control. Optimism is now being replaced by an understanding that the infrastructure for infectious disease surveillance and control has suffered and in some cases become ineffective. A combination of population shifts and movements with changes in environment and human behavior has created weaknesses in the defense systems against infectious diseases in both industrialized and developing countries. These weaknesses have recently come into sharp focus as countries consider preparedness plans for responding to the possible deliberate use of biological agents and recognize the importance of strong public health systems as the first line of defense for infectious disease outbreaks, no matter what their origin.

III. WEAKNESSES FACILITATING EMERGENCE AND RE-EMERGENCE

The weakening of the public health infrastructure for infectious disease control is evidenced by failures such as in mosquito control in Latin America and Asia with the re-emergence of dengue now causing major epidemics; in the vaccination programs in eastern Europe during the 1990s, which contributed to the re-emergence of epidemic diphtheria and polio; and in yellow fever vaccination, facilitating yellow fever outbreaks in Latin America and sub-Saharan Africa, including a large urban outbreak that occurred in Côte d'Ivoire in 2001. It is also clearly demonstrated by the high levels of hepatitis B and the nosocomial transmission of other pathogens such as HIV in the former USSR and Romania, and the nosocomial amplification of outbreaks of Ebola in Zaire, where syringes and failed barrier nursing drove outbreaks into major epidemics.

Population increases and rapid urbanization during this 25-year period have resulted in a breakdown of sanitation and water systems in large coastal cities in Latin America, Asia, and Africa, promoting the transmission of cholera and shigellosis. In 1950, there were only two urban areas in the world with populations greater than 7 million, but by 1990 this number had risen to 23, with increasing populations in and around all major cities, challenging the capacity of existing sanitary systems.

Anthropogenic or natural effects on the environment also contribute to the emergence and re-emergence of infectious diseases. The effects range from global warming and the consequent extension of vector-borne diseases, to ecological changes due to deforestation that increase contact between humans and animals, and also the possibility that microorganisms will breach the species barrier. These changes have occurred on almost every continent. They are exemplified by zoonotic diseases such as Lassa fever first identified in West Africa in 1969 and now known to be transmitted to humans from human food supplies contaminated with the urine of rats that were in search of food, as their natural habitat could no longer support their needs. In Latin America, Chagas disease emerged as an important human disease after mismanagement of deforested land caused triatomine populations to move from their wild natural hosts to involve human beings and domestic animals in the transmission cycle, eventually transforming the disease into an urban infection that can be transmitted by blood transfusion. Other zoonotic diseases include Lyme borreliosis in Europe and North America, transmitted to humans who come into contact with ticks that normally feed on rodents and deer, the reservoir of *Borrelia burgdorferi* in nature; and the Hantavirus pulmonary syndrome in North America. The narrow band of desert in sub-Saharan Africa, in which epidemic *Neisseria meningitidis* infections traditionally occur, has enlarged as drought spread south, so that Uganda and Tanzania experience epidemic meningitis, while outbreaks of malaria and other vector-borne diseases have been linked to the cutting of the rainforests. A 1998 outbreak of Japanese encephalitis in Papua New Guinea has been linked to an extensive drought, which led to increased mosquito breeding as rivers dried into stagnant pools. The virus is now widespread in Papua New Guinea and threatening to move farther east. Buruli ulcer, a poorly understood mycobacterial disease that has emerged dramatically over the past decade, has erupted following significant environmental disturbances, and some evidence suggests that recent explosive increases in Africa are linked to deforestation and subsequent

flooding, or to the construction of dams and irrigation systems.

And finally, human behavior has played a role in the emergence and re-emergence of infectious diseases, best exemplified by the increase in gonorrhoea and syphilis during the late 1970s, and the emergence and amplification of HIV worldwide, which are directly linked to unsafe sexual practices.

IV. FURTHER AMPLIFICATION

The emergence and re-emergence of infectious diseases are also amplified by two major factors—the continuing and increasing evolution of anti-infective (drug) resistance (see Table 32.2), and dramatic increases in international travel. Anti-infective agents are the basis for the management of important public health problems such as tuberculosis, malaria, sexually transmitted diseases, and lower-respiratory infections. Shortly after penicillin became widely available in 1942, Fleming sounded the first warning of the potential importance of the development of resistance. In 1946, a hospital in the United Kingdom reported that 14% of all *Staphylococcus aureus* infections were resistant to penicillin, and by 1950 this had increased to 59%. In the 1990s, penicillin-resistant *S. aureus* had attained levels greater than 80% in both hospitals and the community. Levels of resistance of *S. aureus* to other anti-infectives, and among other bacteria increased with great rapidity. By 1976, chloroquine resistant *Plasmodium falciparum* malaria was highly prevalent in southeastern Asia and 20 years later was found worldwide, as was high-level resistance to two back-up drugs, sulfadoxine-pyrimethamine and mefloquine. In the early 1970s, *Neisseria gonorrhoeae* that was resistant to usual doses of penicillin was just being introduced into Europe and the United States from Southeast Asia, where it is thought to have first emerged. By 1996, *N. gonorrhoeae*

resistance to penicillin had become worldwide, and strains resistant to all major families of antibiotics had been identified wherever these antibiotics had been widely used. Countries in the western Pacific, for example, have registered quinolone resistance levels up to 69%.

The mechanisms of resistance, a natural defense of microorganisms exposed to anti-infectives, include both spontaneous mutation and genetic transfer. The selection and spread of resistant strains are facilitated by many factors, including human behavior in over-prescribing drugs, in poor compliance, and in the unregulated sale by non-health workers. In Thailand, among 307 hospitalized patients, 36% who were treated with anti-infective drugs did not have an infectious disease. The over-prescribing of anti-infectives occurs in most other countries as well. In Canada, it has been estimated of the more than 26 million people treated with anti-infective drugs, 50% were treated inappropriately. Findings from community surveys of *Escherichia coli* in the stool samples of healthy children in China, Venezuela, and the United States suggest that although multiresistant strains were present in each country, they were more widespread in Venezuela and China, countries where less control is maintained over antibiotic prescribing. Animal husbandry and agriculture use large amounts of anti-infectives, and the selection of resistant strains in animals, which then genetically transfer the resistance factors to human pathogens or infect humans as zoonotic diseases, is a confounding factor that requires better understanding. Direct evidence exists that four multiresistant bacteria infecting humans, *Salmonella*, *Campylobacter*, *Enterococci*, and *Escherichia coli*, are directly linked to resistant organisms in animals (WHO Conference on the Medical Impact of the Use of Antimicrobial Drugs in Food Animals, Berlin, 13–17 October 1997).

Infections with resistant organisms require increased length of treatment with more expensive anti-infective drugs or drug combinations, and a doubling of mortality has been observed in some resistant infections. At the same time, fewer new antibiotics reach the market, possibly in part due to the financial risk of developing a new anti-infective drug that may itself become ineffective before the investment is recovered. There is no new class of broad-spectrum antibiotic currently on the horizon. Among the major infectious diseases, the development of resistance to drugs commonly used to treat malaria and tuberculosis is of particular public health concern, as is the emerging resistance to anti-HIV drugs. Even if the pharmaceutical industry were to accelerate efforts to develop new antimicrobials immediately, current

TABLE 32.2 Resistance of common infectious diseases to anti-infective drugs, 1998

Disease	Anti-infective drug	Range (%)
Acute respiratory infection (<i>S. pneumoniae</i>)	Penicillin	12–55
Diarrhea (<i>Shigella</i>)	Ampicilline Trimethoprim Sulfamethoxazole	10–90 9–95
Gonorrhoea (<i>N. gonorrhoeal</i>)	Penicillin	5–98
Malaria	Chloroquine	4–97
Tuberculosis	Rifampicin Isonizid	2–40

trends suggest that some diseases may have very few and, in some cases, no effective therapies within the next 10–20 years. Many important medical and surgical procedures, including cancer chemotherapy, bone marrow and organ transplantation, and hip and other joint replacements, could no longer be undertaken out of fear that the associated compromise of immune function might place patients at risk of acquiring a difficult to treat and ultimately fatal infection.

The role of travel in the spread of infectious diseases has been known for centuries. Because a traveller can be in a European or Latin American capital one day and the next day be in the center of Africa or Asia, humans, like mosquitoes, have become important vectors of disease. During the 1990s, over 500 million people travelled by air each year (World Tourism Organization), and contributed to the growing risk of exporting or importing infection or drug-resistant organisms. In 1988, a clone of multiresistant *Streptococcus pneumoniae* first isolated in Spain was later identified in Iceland. Another clone of multiresistant *S. pneumoniae*, also first identified in Spain, was subsequently found in the United States, Mexico, Portugal, France, Croatia, Republic of Korea, and South Africa. A study conducted by the Ministry of Health of Thailand on 411 exiting tourists showed that 11% had an acute infectious disease, mostly diarrheal, but also respiratory infections, malaria, hepatitis, and gonorrhoea (B. Natth, personal communication). Forced migration such as by refugees is also associated with the risk of re-emergence and spread of infectious diseases. In 1999, more than 7 million people around the world were newly uprooted. Currently, more than 35 million people are refugees or internally displaced persons. In a refugee population estimated to be between 500,000 and 800,000 in one African country in 1994, an estimated 60,000 developed cholera in the first month after the influx, and an estimated 33,000 died.

V. SOLUTIONS

Eradication and regulation may contribute to the containment of infectious diseases, but do not replace sound public health practices that prevent the weaknesses through which infectious diseases penetrate. Eradication was successful for smallpox and is advancing for poliomyelitis with virus transmission interrupted in the Americas, the Western Pacific, and Europe. Eradication or elimination applies to very few infectious diseases—those that have no reservoir other than humans, that trigger solid immunity after infection, and for which there exists an affordable and

effective intervention. The development of powerful new medicines that are safe, affordable, and suitable for single-dose administration in mass campaigns has made it possible for WHO and the international community to launch recent campaigns to eliminate leprosy, lymphatic filariasis, and onchocerciasis and to consider the elimination of schistosomiasis and soil-transmitted helminthiasis in areas where control programmes have succeeded in achieving low transmission.

Attempts at regulation to prevent the spread of infectious diseases were first recorded in 1377 in quarantine legislation to protect the city of Venice from plague-carrying rats on ships from foreign ports. Similar legislation in Europe, and later the Americas and other regions, led to the first international sanitary conference in 1851, which laid down a principle for protection against the international spread of infectious diseases: maximum protection with minimum restriction. Uniform quarantine measures were determined at that time, but a full century elapsed, with multiple regional and inter-regional initiatives, before the International Sanitary Regulations were adopted in 1951. These were amended in 1969 to become the International Health Regulations (IHRs), which are implemented by the WHO.

The IHRs provide a universal code of practice, which ranges from strong national disease detection systems and measures of prevention and control including vaccination, to disinfection and de-ratting. Currently, the IHRs require the reporting of three infectious diseases—cholera, plague, and yellow fever. But when these diseases are reported, regulations are often misapplied, resulting in the disruption of international travel and trade, and huge economic losses. For example, when the cholera pandemic reached Peru in 1991, it was immediately reported to WHO. In addition to its enormous public health impact, however, misapplication of the regulations caused a severe loss in trade (due to concerns for food safety) and travel, which has been estimated as high as \$770 million.

In 1994, an outbreak of plague occurred in India with approximately 1000 presumptive cases. The appearance of pneumonic plague resulted in thousands of Indians fleeing from the outbreak area, risking spread of the disease to new areas. Plague did not spread, but the outbreak led to tremendous economic disruption and concern worldwide, compounded by misinterpretation and misapplication of the IHRs. Airports were closed to airplanes arriving from India, exports of foodstuffs were blocked, and in some countries Indian guest workers were forced to return to India even though they had not been in India for several years before the plague epidemic occurred. Estimates of the cost of lost trade and travel are as

high as \$1700 million. Again, the country suffered negative consequences from reporting an IHR-mandated diseases due to the misapplication of the IHRs.

A further problem with the IHRs is that many infectious diseases, including those which are new or re-emerging, are not covered even though they have great potential for international spread. These range from relatively infrequent diseases such as viral hemorrhagic fevers to the more common threat of meningococcal meningitis.

Because of the problematic application and disease coverage of the IHRs, WHO has undertaken a revision and updating of the IHRs to make them more applicable to infection control in the twenty-first century. Revisions include a considerable broadening of scope to embrace all infectious diseases of international importance, especially new and re-emerging diseases. The present obligation on countries is being broadened to include a clear mechanism for confidential collaboration between the affected country and WHO to verify the presence or absence of a suspected outbreak unofficially reported by the press or electronic media. Modifications also introduce provisions for defining what constitutes a "public health emergency of international concern," thus helping to avoid inappropriate reactions to strictly localized events. It is envisaged that the revised IHRs will become a true global alert and response system to ensure maximum protection against the international spread of diseases with minimum interference with trade and travel.

Eradication and elimination cannot substitute for good public health—rebuilding of the weakened public health infrastructure and strengthening water and sanitary systems; minimizing the impact of natural and anthropogenic changes in the environment; effectively communicating information about the prevention of infectious diseases; and using antibiotics appropriately. The challenge in the twenty-first century

will be to continue to provide resources to strengthen and ensure more cost-effective infectious disease control while also providing additional resources for other emerging public health problems, such as those related to smoking and aging.

Energy transduction processes: from respiration to photosynthesis

Stuart J. Ferguson

University of Oxford

GLOSSARY

aerobic respiration The energetically downhill electron transfer, from a donor molecule or ion to oxygen, which is reduced to water, with concomitant coupled ion translocation and thus generation of an electrochemical gradient.

anaerobic respiration The energetically downhill electron transfer, from a donor molecule or ion to a molecule other than oxygen, or to an ionic species, with concomitant coupled ion translocation and thus generation of an electrochemical gradient. The reduction products of the acceptors can either be released from the cell or, sometimes, used as further electron acceptors.

antiport The transport of a molecule or ion up its chemical or electrochemical gradient with the concomitant movement in the opposite direction, but down its electrochemical gradient, of one or more protons or sodium ions.

bacteriorhodopsin A protein of the cytoplasmic membrane of the halophilic archaebacterium *Halobacterium salinarum* (formerly *halobium*) that has a covalently attached retinal molecule. Absorption of light by the latter pigment results in proton translocation across the membrane.

chemiosmotic mechanism The transduction of energy between two forms via an ion electrochemical gradient (*q.v.*) (usually of protons but sometimes of sodium) across a membrane. Examples of such membranes are the cytoplasmic membranes of bacteria,

the inner mitochondrial membranes of eukaryotes, and the thylakoid membranes of algae.

cytochrome Hemoprotein in which one or more hemes is alternately oxidized and reduced in electron-transfer processes.

electrochemical gradient The sum of the electrical gradient or membrane potential ($\Delta\psi$) and the ion concentration gradient across a membrane (the latter is often defined as ΔpH for protons).

electron acceptor Low-molecular-weight inorganic or organic species (compound or ion) that is reduced in the final step of an electron-transfer process.

electron donor Low-molecular-weight inorganic or organic species (compound or ion) that is oxidized in the first step of an electron-transfer process.

electron transport The transfer of electrons from a donor molecule (or ion) to an acceptor molecule (or ion) via a series of components (a respiratory chain, *q.v.*), each capable of undergoing alternate oxidation and reduction. The electron transfer can either be energetically downhill, in which case it is often called respiration (*q.v.*), or energetically uphill when it is called reversed electron transfer (*q.v.*).

F_0F_1 ATP synthase The enzyme that converts the protonmotive force into the synthesis of adenosine triphosphate (ATP). Protons (or more rarely sodium ions) flow through the membrane sector of the enzyme, known for historical reasons as F_0 , and thereby cause conformational changes, with concomitant ATP synthesis, in the globular F_1 part of

the molecule. In some circumstances the enzyme can generate the proton-motive force at the expense of ATP hydrolysis.

oxidase The hemoprotein that binds and reduces oxygen, generally to water. Oxygen reductase is the function.

oxidative phosphorylation ATP synthesis coupled to a proton or sodium electrochemical gradient (*q.v.*), generated by electron transport, across an energy transducing membrane.

P/O (P/2e) ratio The number of molecules of ATP synthesized per pair of electrons reaching oxygen, or more generally any electron acceptor.

photophosphorylation ATP synthesis coupled to a proton or sodium electrochemical gradient generated by light-driven electron transport, which is often cyclic in bacteria.

proton-motive force The proton electrochemical gradient (*q.v.*) across an energy-transducing membrane in units of volts or millivolts.

quinone Lipid-soluble hydrogen (i.e. proton plus electron) carrier that mediates electron transfer between respiratory chain components.

respiration The sum of electron transfer reactions resulting in reduction of oxygen (aerobically) or other electron acceptor (anaerobically) and generation of proton-motive force.

respiratory chain Set of electron-transfer components, which may be arranged in a linear or branched fashion, that mediate electron transfer from a donor to an acceptor in aerobic or anaerobic respiration (*q.v.*).

redox potential A measure of the thermodynamic tendency of an ion or molecule to accept or donate one or more electrons. By convention, the more negative the redox potential the greater is the propensity for donating electrons and vice versa.

reversed electron transport The transfer of electrons energetically uphill toward the components of an electron-transfer chain that have more negative redox potentials. Such electron transfer can be regarded as the opposite of the respiration (*q.v.*) and is driven by the proton-motive force.

symport The transport of a molecule up its chemical or electrochemical gradient with the concomitant movement, in the same direction but down its electrochemical gradient, of one or more protons or sodium ions.

uniport The transport of an ionic species in direct response to the membrane potential across a membrane.

The Inner Mitochondrial Membrane of the microbial eukaryote and the cytoplasmic membrane of the prokaryote

are the key sites where energy available from processes such as the oxidation of nutrients or from light is converted into other forms that the cell needs. Most prominent among these other forms is ATP and thus these types of membrane are concerned with oxidative phosphorylation (or photophosphorylation).

I. INTRODUCTION

Energy-transducing membranes share many common components, but most importantly they operate according to the same fundamental chemiosmotic principle. This states that energetically downhill reactions that are catalyzed by the components of these membranes are coupled to the translocation of protons (or more rarely sodium ions) across the membranes. The direction of movement is outward from the matrix of the mitochondria or the cytoplasm of bacteria. The consequence of this translocation is the establishment of a proton electrochemical gradient. This means that the matrix of the mitochondria or cytoplasm of the bacteria tends to become both relatively negatively charged (thus, called the N side) and alkaline relative to the other side of the membranes, the intermembrane space in the mitochondria and the periplasm in gram-negative bacteria (and equivalent zone in gram-positive bacteria and archae), which is thus called the P side (Fig. 33.1). This electrochemical gradient is in most circumstances dominated by the charge term, which means that there is often a substantial membrane potential across the membranes, frequently estimated to be on the order of 150–200 mV. In most circumstances, the pH gradient generated by the proton translocation is small, 0.5 unit would be an approximate average value. The membrane potential is added to the pH gradient to give the total gradient, which is usually called the proton-motive force if it is given in millivolts. The conversion factor is such that 0.5 pH unit is approximately equivalent to 30 mV. Strictly speaking, the expression of the gradient as an electrochemical potential requires that units of kJ/mol be used; in practice this is rarely done, which sometimes causes confusion. I use the term proton-motive force in this article.

II. MITOCHONDRIAL ENERGETICS

The best-known machinery for generating the proton-motive force is the mitochondrial respiratory chain. The standard mitochondrial respiratory chain is found, at least under some growth conditions, in eukaryotic microbes. The key point is that as a pair of

FIGURE 33.1 (a) Idealized mitochondrion in a eukaryotic cell and (b) gram-negative bacterium showing the direction of proton translocation linked to an exergonic (energetically downhill) reaction. P means a relatively positive aqueous phase (i.e. outside the inner mitochondrial membrane or the bacterial cytoplasmic membrane); N means a relatively negative aqueous phase (i.e. inside the mitochondrion (the matrix) or the cytoplasm of a bacterium). ↓ represents the ATP synthase enzyme.

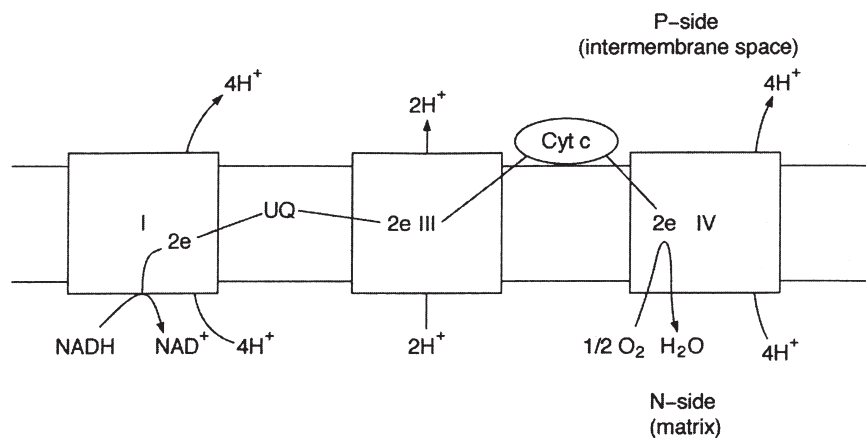

FIGURE 33.2 Considerably *simplified* representation of the proton-translocation stoichiometry, per two electrons, of the mitochondrial respiratory chain. I indicates complex I (otherwise known as NADH dehydrogenase); III, complex III (otherwise known as the ubiquinol-cytochrome *c* oxidoreductase or cytochrome *bc*₁ complex); IV, complex IV (otherwise known as cytochrome *C* oxidase or cytochrome *aa*₃ oxidase); P, positive aqueous phase; and N, negative aqueous phase.

electrons traverses the chain from NADH to oxygen there are three segments (formerly called sites, but this term is inappropriate because it implies equivalence and relates to a very old idea that ATP is made at three sites within the electron-transport chain) where protons can be translocated across the membrane. The first and last of these segments move four protons per two electrons, while the middle segment moves only two (Fig. 33.2) (consideration of the mechanisms of these proton translocations is beyond the scope of this article). Thus, 10 protons are moved per

two electrons moving along the chain from NADH to O_2 . Electrons may enter the chain such that they miss the first proton-translocating segment of the chain; succinate and the intermediates generated during fatty-acid oxidation are the most prominent examples of electron sources for this. In these cases, six protons are translocated per two electrons. The entry of electrons at the third segment would obviously give a translocation stoichiometry of four.

The proton-motive force generated can then be used to drive various uphill reactions. Most prominent is

ATP synthesis. This is achieved by protons flowing back across the membranes and through the ATP synthase enzyme, often called F_0F_1 ATP synthase. There is increasing insight into the mechanism of this enzyme; it appears to function akin to a rotary motor in which the flow of protons through the F_0 is coupled to rotation and structural changes in the F_1 part of the molecule, events that are somehow linked to ATP synthesis. It is not settled how many protons must pass through the ATP synthase to make one ATP molecule; a consensus value adopted here, even though it is not fully confirmed, is three. On the basis of "what goes one way across the membrane must come back the other," it might therefore be thought that the stoichiometry of ATP production per pair of electrons (called the P/O or P/2e ratio) flowing from NADH to oxygen would be 10/3 (i.e. 3.3) for NADH and 6/3 (i.e. 2) for succinate. However, matters are a little more complicated. The combined process of entry of ADP and P_i (phosphate) into mitochondria and the export of ATP to the cytoplasm involves the movement of one proton into the matrix (Fig. 33.3). Thus for each ATP made, the expected stoichiometry is $10/(3 + 1) = 2.5$ for NADH and $6/(3 + 1) = 1.5$ for succinate. These values differ from the classic textbook values of 3 and 2, respectively, but they are rapidly becoming accepted.

It was generally thought that eukaryotes were only capable of aerobic respiration. However, there is now evidence for a form of mitochondrial anaerobic respiration

in which nitrate is reduced to nitrous oxide (more typically a prokaryotic characteristic, see the following) and for a novel type of mitochondrion from the ciliate protist *Nyctotherus ovalis* that reduces protons to hydrogen. In both these examples, electrons are derived from NADH.

III. BACTERIAL ENERGETICS

Many species of bacteria employ a respiratory chain similar to that found in mitochondria in order to generate a proton-motive force. However, there are many more types of electron donor and acceptor species that can be used by bacteria (eukaryotes are restricted to the oxidative breakdown of reduced carbon compounds), and various forms of anaerobic respiration are widespread. A further general difference between bacteria and microbial eukaryotes is that in the former the proton-motive force can drive a wider range of functions and be generated in more diverse ways than in the latter. Thus, functions alongside ATP synthesis (for which the enzyme is very similar to that found in mitochondria), such as driving of many active transport processes and the motion of the flagella, are important processes that depend on the proton-motive force in many organisms (Fig. 33.4).

A common mode of active transport is known as the symport; the classic example of this is the lactose-proton symporter coded for by the *lacY* gene of the *lac* operon of *E. coli*. In this case, a transmembrane protein translocates together a proton down its electrochemical gradient and a lactose molecule up its concentration gradient (Fig. 33.5); the exact mechanism is presently unknown. There are cases known where Na is the translocated ion. A second type of transport system is the antiport (Fig. 33.5). Here the movement via a protein of the proton down its electrochemical

FIGURE 33.3 Charge movement, associated with ATP synthesis and translocation of adenine nucleotides and phosphate across the inner mitochondrial membrane. The stoichiometry of proton translocation through the ATP synthase is commonly taken to be 3 but this is not a definite value. The translocated protons are not believed to pass through the active site of the ATP synthase enzyme. Note that the adenine nucleotide exchange moves one positive charge into the matrix per nucleotide exchanged and the operation of the phosphate transporter effectively moves the chemical part of the proton (but not the charge) into the matrix. Thus, in combination, the two transporters move one positive charge into the mitochondrion per ATP synthesized and returned to the P phase. Note that these transporters do not operate in bacterial ATP synthesis.

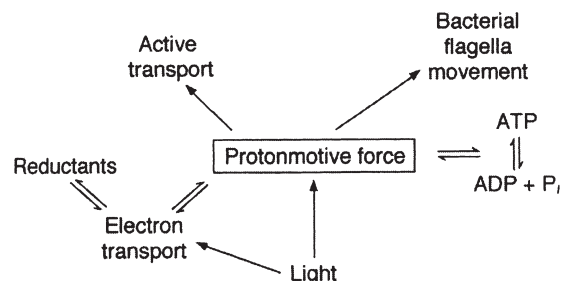

FIGURE 33.4 The central role of the proton-motive force in linking diverse reactions. Note that the direct generation of proton-motive force from light is unusual, but is exemplified by the proton-pumping bacteriorhodospin protein found in halobacteria. Normally light drives electron-transport processes, which in turn generate the proton-motive force.

FIGURE 33.5 The three common modes of substrate transport across the bacterial cytoplasmic membrane.

gradient is obligatorily linked to the movement of another species, typically an ion, in the opposite direction and up its electrochemical gradient. The third type, uniport, is the case where an ion moves in direct response to the membrane potential and is probably rarer than the other two examples in the prokaryotic world.

It is important to appreciate that not all transport processes across the bacterial cytoplasmic membrane are directly driven by the proton-motive force. Some transport reactions are driven directly by ATP. Notable among such systems are ABC (ATP binding cassette) transporters.

A more subtle aspect of prokaryotic energetics is that in some species of bacteria the proton-motive force must drive reversed electron transport under some circumstances (see later).

A common misconception when multiple functions of the proton-motive force are discussed is that this force can be divided (e.g. 100 mV for ATP synthesis and 50 mV for flagella motion). This notion is incorrect because the proton-motive force across a membrane has a single value at any one time and it is the magnitude of this force that is acting simultaneously on all energy-transducing units, be they ATP synthases, active transporters, or flagella.

IV. PRINCIPLES OF RESPIRATORY ELECTRON-TRANSPORT LINKED ATP SYNTHESIS IN BACTERIA

In principle, energy transduction on the cytoplasmic membrane is possible if any downhill reaction is coupled to proton translocation. The most familiar examples are probably those that also occur in mitochondria, for example, electron transfer from NADH to oxygen or from succinate to oxygen. In these cases, the electrons pass over a sizeable redox drop (Table 33.1). In contrast to mitochondria, various species of bacteria

TABLE 33.1 Approximate Standard Redox Potentials of Some Electron-Donor and -Acceptor Couples Used in Respiratory Processes^a

Couple	E°' (mV)
N ₂ O/N ₂	+1360
NO/N ₂ O	+1180
O ₂ /H ₂ O	+820
NO ₃ ⁻ /NO ₂ ⁻	+430
NO ₂ ⁻ /NH ₄ ⁺	+360
NO ₂ ⁻ /NO	+350
fumarate/succinate	-30
methanol/formaldehyde	-180
NAD ⁺ /NADH	-320
CO ₂ /formate	-430
CO ₂ /CO	-540

^aRedox potential refers to the standard state (1M concentrations for solutes and 1atm pressure for gases). Conditions experienced by cells may vary significantly from these and thus the actual redox potentials of the couples should be calculated from the Nernst equation and may differ substantially from those in this table.

can use a wide variety of electron donors and acceptors. The fundamental principle is that the redox drop should be sufficient for the electron transfer to be coupled to the translocation of protons across the cytoplasmic membrane. Table 33.1 shows that such sizeable drops are associated with the aerobic oxidation of hydrogen, sulfide, carbon monoxide, and methanol, to cite just a few electron donors. Anaerobic respiration is also common with many suitable pairings of reductants and oxidants (e.g. Table 33.1). Thus NADH can be oxidized by nitrate, nitrite, nitric oxide, or nitrous oxide. The flow of electrons to these acceptors, each of which (other than nitrate) is generated by the reduction of the preceding ion or molecule, is the process known as denitrification. In *E. coli* under anaerobic conditions, formate is frequently an electron donor, and nitrate and nitrite are the acceptors, with the latter being reduced to ammonia (Table 33.1) rather than to nitric oxide, as occurs in denitrifying bacteria. A wide variety of electron-transport components, including many different types of cytochrome are involved in catalyzing these reactions. The mechanisms whereby electron transport is linked to the generation of the proton-motive force are frequently complex. However, nitrate respiration (Fig. 33.6) provides an example of one of the simplest mechanisms that corresponds to Mitchell's original redox loop mechanism.

An important point is that the consideration of the energy drop between the donor and acceptor (Table 33.1) is only a guide as to whether proton translocation, and thus ATP synthesis, can occur and,

FIGURE 33.6 A simple mechanism for generating the proton-motive force, the bacterial nitrate reductase system. Oxidation of ubiquinol (UQH_2) to ubiquinone (UQ) at one side of the membrane is accompanied by release of protons to the P side and translocation of the electrons towards the N side, where they combine with protons and nitrate to produce nitrite. Overall, the process effectively translocates two protons per two electrons across the membrane. The mitochondrial electron-transport chain (see Fig. 33.2) involves more complex mechanisms for proton translocation. DH_2 is an unspecified donor to the ubiquinone, and D is the product of oxidizing DH_2 .

if so, with what stoichiometry. Thus while many bacterial species can form a respiratory chain with considerable similarity to that found in mitochondria, others vary from this pattern. Notable here is *Escherichia coli*, which always lacks the cytochrome bc_1 complex, and which, following some growth conditions, has cytochrome bo as the terminal oxidase, but which under others has cytochrome bd . The consequence is that when the former proton-pumping oxidase is operating only eight protons are translocated per pair of electrons flowing from NADH to oxygen, while with the latter oxidase the stoichiometry would be six. The corresponding stoichiometry for mitochondria is ten. This example illustrates the important point that it is not just the energy drop between a donor and an acceptor that is important, but also the details of the components (or molecular machinery) in between. Another example is methanol to oxygen. Periplasmic oxidation of methanol feeds electrons into the electron-transport chain close to the terminal oxidase, yet energetic considerations alone would indicate that electrons could span more proton-translocating sites, just as they do when succinate is the electron donor (compare the redox potentials for fumarate–succinate and methanol–formaldehyde; Table 33.1). A final example to consider is the case in which both the electron donor and acceptor are in the periplasm and they are connected purely by periplasmic components. In such a case, which applies to

methanol (as donor) and nitrous oxide (N_2O as acceptor), the electrons do not pass through any proton-translocating complex. Thus, no proton translocation would occur no matter what the redox drop between the two components.

It is not necessary for electrons to flow over such a large energy drop as they do when they pass from NADH to oxygen (Table 33.1) in order to generate a proton-motive force. Thus, if the driving force associated with a reaction was very small, it might still be energetically possible for the passage of two electrons from a donor to an acceptor to cause the translocation of just one proton. If three protons are required for the synthesis of ATP, then the ATP yield stoichiometry would be 0.166 per electron flowing from electron donor to acceptor. This seemingly bizarre stoichiometry is not only energetically possible but also mechanistically possible because the chemiosmotic principle involves the delocalized proton-motive force that is generated by all the enzymes of the membrane and also consumed by them all. There is no case known that matches this extreme; nevertheless, there may well be organisms yet to be discovered that have such low stoichiometries of ATP synthesis.

One example of the lowest known stoichiometries of ATP synthesis per pair of electrons reaching the terminal electron acceptor (oxygen) occurs in *Nitrobacter*. Table 33.1 shows that the redox drop is small between nitrite and oxygen. This organism also illustrates the versatility and subtlety of the chemiosmotic mode of energy transduction. *Nitrobacter* species oxidize nitrite to nitrate at the expense of the reduction of oxygen to water in order to sustain growth. The energy available as a pair of electrons flows from nitrite to oxygen is sufficient to translocate two protons (a more detailed consideration of how this is done is outside the scope of this chapter). This means, recalling the current consensus that three protons are needed for the synthesis of one ATP molecule, that the ATP yield stoichiometry would be $0.66/2e$. *Nitrobacter* also illustrates another important facet of energy transduction in the bacterial world. The organism is chemolithotrophic, which means that it grows on nitrite as the source not only of ATP but also of reductant (NADPH), which is required for reducing CO_2 into cellular material. Energetic considerations immediately show that nitrite cannot reduce NADP directly. What happens in the cell is that a minority of the electrons originating from nitrite are driven backward up the electron-transfer system to reduce NAD(P) to NAD(P)H. This is achieved by the inward movement of protons reversing the usual direction of electron movement (Fig. 33.7). This reversed electron-transport process is an important phenomenon in

FIGURE 33.7 Reversed electron transport illustrated by the example of *Nitrobacter*. The majority of electrons derived from nitrite flow energetically downhill to oxygen via a cytochrome oxidase, which generates a protonmotive force. A minority of electrons is driven energetically uphill by the protonmotive force so as to reduce NAD^+ to NADH . Note that in this diagram no proton stoichiometry values are implied.

a variety of bacteria, especially those growing in the chemolithotrophic mode.

Most studies of electron transport-linked ion translocation have been done with species of eubacteria. However, the same fundamental process also occurs in archaeobacteria, although with some novel features that reflect some of the extreme growth modes tolerated by these organisms. For example, a key step in methane formation by methanogenic bacteria is electron transfer from hydrogen or other reductant to a small molecule contains a disulfide bond. The latter is reduced to two sulfides and the overall process is coupled to the translocation of protons across the cytoplasmic membrane. The proton-motive force thus set up can be used to drive ATP synthesis. Interestingly the ATP synthase in archaeobacteria shows significant molecular differences from its counterpart in eubacteria and mitochondria, but is believed to function according to the same principle.

V. GENERATION OF THE ION ELECTROCHEMICAL GRADIENT OTHER THAN BY ELECTRON TRANSPORT

A. ATP hydrolysis

Organisms that are incapable of any form of respiration still require an ion electrochemical gradient across the cytoplasmic membrane for purposes such as nutrient uptake. One way in which this requirement can be

met is for some of the ATP synthesized by fermentation to be used for ATP hydrolysis by the FoF_1 ATPase. This means that this enzyme works in the reverse of its usual direction and pumps protons out of the cell. Thus there are many organisms that can prosper in the absence of any electron-transport process, either as an option or as an obligatory aspect of their growth physiology.

B. Bacteriorhodopsin

A specialized form of light-driven generation of proton-motive force, and hence of ATP, occurs in halobacteria; these organisms are archaeobacteria. The key protein is bacteriorhodopsin, which is a transmembrane protein with seven α -helices that has a covalently bound retinal. The absorption of light by this pigment initiates a complex photocycle that is linked to the translocation of one proton across the cytoplasmic membrane for each quantum absorbed. Bacteriorhodopsin is one of a family of related molecules. Another, halorhodopsin, is structurally very similar and yet catalyzes the inward movement of chloride ions driven by light.

C. Methyl transferase

One step of energy transduction in methanogenic bacteria involves an electron-transfer process (see earlier). Another important process in methanogens is the transfer of a methyl group from a pterin to a thiol compound. This exergonic (energetically downhill) reaction is coupled to ion, in this case sodium, translocation across the cytoplasmic membrane.

D. Decarboxylation linked to ion translocation

In the bacterial world, the electrochemical gradients can be generated by diverse processes other than electron transport or ATP hydrolysis. For example, *Propionigenium modestum* grows on the basis of catalyzing the conversion of succinate to propionate and carbon dioxide. One of the steps in this conversion is decarboxylation of methyl-malonyl coenzyme A (CoA) to propionyl CoA. This reaction is catalyzed by a membrane-bound enzyme that pumps sodium out of the cells, thus setting up a sodium electrochemical gradient (or sodium-motive force). This gradient in turn drives the synthesis of ATP as a consequence of sodium ions reentering the cells through a sodium-translocating ATP synthase enzyme. Apart from illustrating that sodium, instead of proton circuits, can be used for energy transduction in association with the

FIGURE 33.8 Two examples of generation of proton-motive force by end-product extrusion from fermenting bacteria.

bacterial cytoplasmic membrane, this organism also illustrates that the stoichiometry of ATP synthesis can be less than one per CO_2 formed. It is believed that each decarboxylation event is associated with the translocation of two sodium ions and the synthesis of ATP with three. Thus non-integral stoichiometry is consistent with the energetics of decarboxylation and ATP synthesis. This is an important paradigm to appreciate; the underpinning growth reaction for an organism does not have to be capable of supporting the synthesis of one or more integral numbers of ATP molecules.

E. Metabolite ion-exchange mechanisms

Another example of the generation of a proton-motive force is ion exchange across the membrane. For example, in fermenting bacteria there is evidence that under some conditions an end-product of metabolism, lactic acid, leaves the cell together (i.e. in symport) with than one proton; this results in the generation of a proton-motive force (Fig. 33.8). A second example is provided by *Oxalobacter formigenes*, in which the entry of the bivalent anion oxalate is in exchange for the exit of the monovalent formate ion generated by decarboxylation of the oxalate, leading to the net generation of membrane potential (Fig. 33.8). This seems to be the principal mode of generating membrane potential in this organism.

VI. PHOTOSYNTHETIC ELECTRON TRANSPORT

Prokaryotic photosynthesis involves a cyclic electron-transport process in which a single photosystem captures light energy and uses it to drive electrons around the cycle (Fig. 33.9). The consequence of this cyclic

FIGURE 33.9 An oversimplified outline of the cyclic electron-transport process of photosynthetic bacteria. There are two types of reaction centers, depending on the organism. The molecular composition of the system depends on the organism. Two components contribute to the generation of the proton-motive force.

electron flow is the generation of the proton-motive force. There are two types of photosystem found in prokaryotes. One is related to the water-splitting photosystem that is found in plants; typically this bacterial photosystem is found in organisms such as *Rhodobacter sphaeroides*. The second type of photosystem is closely related to the second photosystem of plants, the one that is concerned with the generation of NADPH. *Heliobacter* is an example of an organism carrying this type of center. Some microorganisms have both of these photosystems, arranged to operate in series as in plants. In this group are the prokaryotic blue-green algae and the eukaryotic algae.

VII. ALKALIPHILES

An interesting unresolved problem relates to energy transduction in the alkaliphilic bacteria. The problem is straightforward. These organisms can grow in an environment with a pH as high as 11 or 12. A cytoplasmic pH even as high as 9 means that the pH gradient could be as much as 3 units (equivalent to 180 mV) the wrong way around in the context of the chemiosmotic mechanism. The membrane potential always seems to be larger than 180 mV, but the total proton-motive force can be very low (e.g. around 50 mV). For some organisms that use a conventional proton-translocating respiratory chain and ATP synthase, it is not understood how they survive energetically. In other organisms, there is evidence for the role of a sodiummotive force. This would sidestep the problem of the adverse proton concentration gradient.

Enteropathogenic bacteria

Farah K. Bahrani-Mougeot and Michael S. Donnenberg

University of Maryland

GLOSSARY

bacteriophage A virus that infects bacteria.

colitis Inflammation of the large intestine (colon).

cytotoxins Bacterial products that damage cells.

diarrhea Increase in the frequency of bowel movement and decrease in the consistency of stool.

dysentery Inflammatory disease of the large bowel with severe abdominal cramps, rectal urgency, and pain during stool passage and the presence of blood, pus, and mucus in stool.

enteritis Inflammation of the small intestine.

enterotoxins Bacterial products that cause fluid secretion from intestinal cells.

fimbriae (or pili) Rigid rod surface organelles with diameters of about 2–7 nm in gram-negative bacteria that often mediate bacterial adherence to host cells.

flagellae Ropelike surface organelles of 15–20 nm in diameter that provide bacteria with motility and the ability to move toward nutrients and away from toxic substances (chemotaxis).

gastritis Inflammation of the stomach.

pathogenicity island Segment of DNA that is foreign to the bacterial host and carries virulence genes.

plasmid Extrachromosomal self-replicating DNA element.

type III secretion pathway A specialized protein secretion system, responsible for export of virulence determinants by some gram-negative bacterial pathogens and symbionts of animals and plants.

Some of the proteins secreted by this pathway are translocated by the bacteria into host cells.

type IV fimbriae Special type of fimbriae produced by certain pathogenic gram-negative bacteria. These fimbriae have subunits with different primary structures and often different morphologies from common fimbriae.

Enteric Infections are caused by a variety of microorganisms, including bacterial pathogens. Among these infections, diarrheal diseases are a major cause of mortality in the children of Third World countries, due to malnutrition, poor personal hygiene, and insufficient environmental sanitation. In industrialized countries, diarrhea may result from foodborne outbreaks and is common in day care centers, hospitals, and chronic care institutions, among homosexual men and immunocompromised patients. Diarrhea can result from inflammatory infections in the colon and/or small intestine caused by pathogens, such as *Shigella*, *Salmonella*, and *Campylobacter*, or noninflammatory infections in the small intestine by pathogens such as *Vibrio* and enterotoxigenic *Escherichia coli*. Diarrhea can also result from ingestion of preformed toxins, produced by bacteria such as *Clostridium perfringens* and *Bacillus cereus*. In addition, infections by enteropathogenic bacteria may cause systemic syndromes, such as typhoid fever caused by *Salmonella typhi*. Another form of enteric infection, gastritis, results exclusively from infections with *Helicobacter pylori*. We will briefly review the epidemiology, pathogenesis, and clinical features of the most important bacterial enteric pathogens of humans.

I. BACTERIAL AGENTS OF INFLAMMATORY DIARRHEA

In the majority of cases, inflammatory diarrhea in the distal small bowel and colon occurs in response to bacterial invasion of the intestinal tissues (Table 34.1). However, in some infections, enterocolitis can be an outcome of bacterial toxicity without invasion. Causative agents of these infections include the following.

A. *Shigella* spp.

Shigella, the major etiologic agent of bacillary dysentery, is traditionally divided into four species based on biochemical and serological characteristics. These

species include *S. dysenteriae*, *S. flexneri*, *S. sonnei*, and *S. boydii*. However, techniques such as multilocus enzyme electrophoresis have revealed that all *Shigella* strains are actually encompassed within the species *E. coli*. Clinical syndromes of shigellosis include a mild watery diarrhea, which is often followed by severe dysentery with blood, mucus, and inflammatory cells in feces. The incubation period ranges from 6 h to 5 days. Epidemiological studies show that *Shigella* is transmitted by the fecal–oral route or by contaminated food and water. As few as 100 organisms can cause infection in an adult.

Shigella invades the colonic mucosa and this invasion involves entry and intercellular dissemination. Bacteria enter the cells by a micropinocytic process,

TABLE 34.1 Epidemiology and clinical characteristics of bacterial enteric pathogens

Pathogen	Route of transmission	Site of infection	Clinical syndrome
<i>B. cereus</i>	Foods such as fried rice and vanilla sauce	Small intestine	Watery diarrhea Vomiting Abdominal cramps
<i>C. jejuni</i>	Contaminated food and water Fecal–oral	Colon Small intestine	Watery diarrhea Dysentery
<i>C. difficile</i>	Environmental contamination with spores Fecal–oral	Colon	Watery diarrhea Pseudomembranous colitis
<i>C. perfringens</i>	Foods such as meat, turkey and chicken	Small intestine	Watery diarrhea Necrotic enteritis
EAEC ^a EHEC ^b	? Food contaminated with cattle feces Person–person contact	Small intestine Colon	Watery and mucoid diarrhea Diarrhea Hemorrhagic colitis Hemolytic uremic syndrome
EIEC ^c	Contaminated food and water Fecal–oral	Colon	Watery diarrhea Dysentery
EPEC ^d	Person–person contact	Small intestine	Watery diarrhea
ETEC ^e	Contaminated food and water	Small intestine	Watery diarrhea
<i>H. pylori</i>	Fecal–oral (?) Person–person contact (?)	Stomach	Gastritis Peptic ulcer Gastric cancer
<i>Salmonella</i> (nontyphi)	Contaminated food and water Animal–person contact	Small intestine Colon	Watery diarrhea Dysentery
<i>S. typhi</i> <i>Shigella</i>	Contaminated food and water Fecal–oral Contaminated food and water Person–person contact	Systemic Colon	Typhoid fever Watery diarrhea Dysentery
<i>S. aureus</i>	High salt- or high sugar-containing foods	Small intestine	Watery diarrhea Vomiting
<i>V. cholerae</i>	Contaminated food and water	Small intestine	Rice-water diarrhea
<i>Y. enterocolitica</i>	Contaminated food Person–pig contact	Small intestine Systemic	Acute diarrhea Enterocolitis Mesenteric adenitis

^eEnterotoxigenic *E. coli*.

which requires polymerization of actin at the site of entry. Shortly after entry, bacteria lyse the phagocytic vacuole and move into the cytoplasm where they multiply. Within the cytoplasm, *Shigella* recruits actin microfilaments at one pole of the bacterium, which leads to the formation of a polymerized actin tail behind the bacterium and, consequently, movement of the bacteria (Fig. 34.1). The movement of the bacteria leads to the formation of cell membrane protrusions that extend from one cell into the adjacent cell and allow dissemination of bacteria without their release into the extracellular environment. The ability of *Shigella* to spread from cell to cell is measured *in vitro* by the formation of plaques on a confluent cell monolayer (plaque assay) and *in vivo* by formation of keratoconjunctivitis in guinea pigs (Sereny test).

All of the genes required for *Shigella* invasion are carried on a 200-kb virulence plasmid. A 30-kb fragment contains the genes that encode secreted proteins called IpaA, B, C, and D, the chaperones for these proteins called IpGs, and a specialized type III secretion system for these proteins called Mxi-Spa. Several other proteins that might be important in the entry process are also secreted by the Mxi-Spa machinery. This machinery becomes activated upon contact of bacteria with the host epithelial cells. The *icsA* (*virG*) gene, which confers the ability of *Shigella* to spread from cell to cell, is located approximately 40 kb away from the *ipa-ipg-mxi-spa* region.

FIGURE 34.1 Actin tail formation by *Shigella flexneri*. Actin microfilaments are polymerized at one end of the bacterium and help it to move within the host cell cytoplasm. Bacteria are stained in red and actin in green. The areas where bacteria and actin colocalize appear in yellow (courtesy of Coumarin Egile and Philippe J. Sansonetti) (Plate 6).

Following secretion, IpaB and IpaC form a complex, which triggers recruitment of actin at the site of bacterial entry by a mechanism that involves the small host G protein, Rho. IpaA contributes to the entry process by interacting with other cytoskeletal proteins, such as vinculin and α -actinin. Contact with macrophages results in delivery of IpaB into the cytoplasm of macrophages where IpaB induces programmed cell death and release of interleukin-1. Release of this cytokine triggers a cascade of proinflammatory responses, which opens intercellular junctions and destabilizes the epithelia, thus facilitating bacterial invasion and ulceration of the colon.

Infections due to *S. dysenteriae* are more severe and more likely to lead to complications than are infections with other *Shigella* species. *S. dysenteriae* produces a lethal cytotoxin, called Shiga toxin. This toxin is composed of an enzymatically active A subunit and five B subunits that mediate binding of the toxin to target cell receptors. The toxin functions by cleaving 28S rRNA of eukaryotic cells and inhibiting protein synthesis. Shiga toxin may play a role in manifestations of hemolytic uremic syndrome, an occasional consequence of shigellosis.

B. Enteroinvasive *E. coli*

E. coli is commonly regarded as a harmless commensal of the intestines of humans. However, at least six varieties have been identified that possess specific pathogenic mechanisms allowing them to cause diarrhea. These pathogens include enteroinvasive *E. coli* (EIEC). EIEC is closely related to *Shigella* spp. in biochemical and serological characteristics, pathogenic mechanisms, and virulence determinants (see preceding) (Tables 34.2 and 34.3). EIEC is identified as *E. coli* based on its biochemical profile but is distinguished from other strains of *E. coli* based on genotypic and phenotypic characteristics of *Shigella* spp. Therefore, the Sereny test and plaque assay are appropriate tests for identification of EIEC.

Like *Shigella* spp., EIEC is transmitted by contaminated food and water. The infectious dose, however, is 2–3 logs higher than that for *Shigella* infection. Therefore, transmission from person to person is likely less than is the case for *Shigella*. Infection with EIEC leads to watery diarrhea, with dysentery syndrome in only some of the patients.

C. Nontyphoidal *Salmonella*

Salmonella spp. other than *Salmonella typhi* are the cause of salmonellosis in humans. There are over 2000 serotypes of *Salmonella* that infect a wide range of

hosts, from humans to domestic animals, birds, reptiles, and insects. Most of the *Salmonella* serotypes associated with human infections belong to subgroup 1 of the six subgroups of *Salmonella enterica*. Many serotypes are species-specific; thus, a particular serotype may be nonpathogenic in one host species and cause severe infection in another.

Gastroenteritis is the most common manifestation of *Salmonella* infections. Diarrhea begins 8–48 h after ingestion of contaminated food and lasts for 3–7 days. Infection is often food-borne and associated with consumption of foods of animal origin, such as chicken, raw milk, and undercooked eggs. The infectious dose ranges from 10⁵ to 10¹⁰ organisms and depends on serotype, source of infection, and host factors. Food-borne salmonellosis seems to be predominantly a disease of industrialized countries. Infections can also be transmitted by the fecal–oral route, particularly among homosexual men. Immunocompromised

hosts, such as HIV-infected individuals, are more prone to *Salmonella* infections. In these patients, nontyphoidal *Salmonella* usually causes bacteremia.

Salmonella spp. invade mucosal cells of the small intestine by a bacterial-mediated endocytosis process similar to *Shigella* entry. Bacteria stimulate signal transduction pathways in epithelial cells that lead to cytoskeletal rearrangements and membrane ruffling, similar to those induced by growth factors on mammalian cells. Membrane ruffling results in uptake of bacteria into cells. Unlike *Shigella*, *Salmonella* remains in membrane-bound vacuoles, modifies the pH of the phagolysosome, and multiplies. The organisms can also be taken up by macrophages, where they multiply and penetrate into deeper tissues (see the section following on *S. typhi*).

Most of the research on the molecular genetic basis of *Salmonella* invasion has been done on *S. typhimurium*. The genes that confer the ability of *Salmonella* to

invade are located on a 40-kb pathogenicity island, called SPI-1, at the 63 min of *S. typhimurium* chromosome. SPI-1 encodes the components of a type III secretion pathway, called Inv-Spa, and the Sip proteins secreted via this machinery. Sip proteins have functions similar to *Shigella* Ipa proteins in the process of entry and induction of proinflammatory response and tissue destruction (see preceding section on *Shigella*).

Lipopolysaccharide (LPS) is another factor involved in invasiveness of *Salmonella*. Rough mutants with short O-side chains are less virulent. *Salmonella* also produces several adhesins, which might facilitate attachment to epithelial cells prior to penetration. In addition, nontyphi *Salmonella* strains produce an enterotoxin that has cytoskeleton-altering activity.

Salmonella strains induce secretion of cytokines such as IL-8 from epithelial cells. IL-8 is a chemoattractant for polymorphonuclear leukocytes (PMNs) and stimulates transmigration of PMNs through epithelial cell tight junctions into the intestinal lumen. The passage of PMNs through cellular junctions can lead to fluid leakage and consequent diarrhea.

D. *Campylobacter* spp.

Campylobacters are slender, spirally curved gram-negative rods, carrying a relatively small (1.6×10^6 bp) AT-rich genome that has been already sequenced. These organisms are microaerophilic, thermophilic, and require complex media for growth. Campylobacters are one of the most commonly reported causes of diarrhea worldwide. Infections with these organisms usually result in inflammatory dysentery-like diarrhea in adults of industrialized nations and watery diarrhea in children of developing countries. Campylobacters can also cause systemic disease. *C. jejuni* and *C. fetus* are the prototypes for diarrheal and systemic infections, respectively.

Campylobacter spp. are found in the gastrointestinal tracts of most domesticated mammals and fowls. Transmission occurs by contaminated food or water or by oral contact with feces of infected animals or humans. The organism cannot tolerate drying or freezing, thus being limited in transmission. Infections occur all year long, with a sharp peak in summer. The infectious dose can be as small as 500 or as high as 10^9 organisms, depending on the source of infection. The incubation period ranges from one to seven days and the duration of the illness is usually one week, with occasional relapses in untreated patients.

Campylobacter jejuni causes inflammation in both the colon and the small intestine. The resulting nonspecific

colitis can be mistaken for acute ulcerative colitis. The inflammatory process can be extended to the appendix, mesenteric lymph nodes, and gall bladder. Bacteremia can also occur in some cases. Infections with *C. jejuni* may be followed by noninfectious complications, such as Guillain-Barre syndrome (GBS), an acute disease of peripheral nerves, and reactive arthritis.

Inflammation and bacteremia caused by *C. jejuni* suggest tissue invasion by this organism. Invasion seems to be linked to the presence of flagellae. Flagellae enable the organisms to move along the viscous environments and penetrate the intestinal mucosa. Binding of *C. jejuni* to host epithelial cells leads to bacterial uptake by a complex mechanism that remains controversial. Bacteria also penetrate the underlying lymphoid tissue and survive within the macrophages.

Campylobacter jejuni strains also produce several toxins. These toxins include a heat-labile cholera-like enterotoxin (CLT), which correlates with watery diarrhea, a cytolethal distending cytotoxin (CLDT), which alters the host cytoskeleton, and a hemolysin(s).

Campylobacter fetus causes febrile systemic illness more often than diarrheal infections. This organism has a tropism for vascular sites, thus causing bacteremia. The organism uses lipopolysaccharide (LPS) and a surface (S) layer protein, which functions as a capsule, to resist phagocytosis and serum-killing. *C. fetus* can disseminate to cause meningoencephalitis, lung abscess, septic arthritis, and urinary tract infections.

E. *Clostridium difficile*

Clostridium difficile is a gram-positive anaerobic spore-forming bacillus. This organism is widespread in the environment and is found in the intestines of several mammals, including humans. *C. difficile* is the most common recognized cause of diarrhea in hospitals and chronic care facilities in developed countries. Antibiotic therapy disrupts the normal flora of the colon and allows colonization or proliferation of *C. difficile*. Infection occurs by ingestion of spores from the environment. The spores resist the gastric acid and germinate into the vegetative form in the colon. The symptoms of disease range from mild diarrhea to severe pseudomembranous colitis. Infection with *C. difficile* is more common in the elderly, whereas neonates are resistant to colonization by this organism.

Pathogenic strains of *C. difficile* produce two very large toxins: toxin A and toxin B. Toxin A is a cytotoxin with a molecular weight of 308 kDa. This toxin stimulates cytokine production by macrophages and infiltration of PMNs, which results in the inflammation seen

in pseudomembranous colitis. Toxin B is a protein of 207 kDa that also possesses cytotoxic activity. This toxin has glucosyltransferase activity that catalyzes transfer of glucose to the small GTP-binding protein, Rho. Modification of Rho leads to actin cytoskeletal disruption, which results in rounding of the cells. *C. difficile* also produces hydrolytic enzymes, such as hyaluronidase, gelatinase, and collagenase, which might contribute to destruction of connective tissue and subsequent fluid accumulation.

II. BACTERIAL AGENTS OF NONINFLAMMATORY DIARRHEA

The noninflammatory watery diarrhea caused by bacteria is usually associated with the production of an enterotoxin after bacterial colonization of the small intestine or with the presence of preformed enterotoxins in food. Occasionally, bacteria can cause a drastic effect on intestinal epithelial cells in the absence of an enterotoxin. This category of diarrhea is caused by the following.

A. *Vibrio cholerae*

Vibrio cholerae belongs to the family *Vibrionaceae* and has been the cause of seven cholera pandemics since 1817. It is transmitted by contaminated food and water. Food-borne transmission often occurs by ingestion of raw or undercooked shellfish. Since the acid-sensitive bacteria must pass through the stomach to colonize the small intestine, a high inoculum of 10^9 organisms is required to cause disease. The diarrhea can be extremely severe, with characteristic "rice water" stools, which can lead to rapid dehydration, circulatory collapse, and death.

Cholera is caused by toxigenic strains of *V. cholerae* O1 and O139 Bengal. The O1 strains can be divided into E1 Tor and classical biotypes that are epidemiologically distinct. *V. cholerae* O139 is a new strain that caused a major epidemic in 1992 in India in a population which was already immune to *V. cholerae* O1 strains. The non-O1 serogroups of *V. cholerae* cause cholera and dysentery but have not been linked to cholera epidemics.

Vibrio cholerae secretes cholera toxin (CT), which is responsible for the characteristic secretory diarrhea. CT is an enterotoxin that binds to enterocytes via five B subunits that facilitate the entry of the enzymatically active A subunit. The A subunit then catalyzes the ADP-ribosylation of the GTP binding protein, $G_s\alpha$, which results in activation of adenylate cyclase,

accumulation of cAMP in enterocytes, and increase in secretion of chloride and water. Increased release of water into the intestinal lumen leads to secretory diarrhea. CT is encoded by the *ctxAB* genes carried on a filamentous bacteriophage. The receptor for the phage is a type IV fimbria, called the toxin-coregulated pilus (TCP), which is an essential colonization factor of *V. cholerae*. The gene encoding TCP is located on a 40-kb pathogenicity island (PI). This PI is associated with pandemic and epidemic strains of *V. cholerae*.

Vibrio cholerae O1 also produces two other toxins, called the zonula occludens toxin (Zot) and the accessory cholera enterotoxin (Ace). Zot affects the structure of the intercellular tight junction, zonula occludens. Ace is postulated to form ion-permeable channels in the host cellular membrane. The role of these toxins in pathogenesis is unknown.

B. Enteropathogenic *E. coli*

Enteropathogenic *E. coli* (EPEC) is an important cause of diarrhea in infants less than 2 years of age. EPEC is transmitted by the fecal-oral route by person-to-person contact. The infection occurs more frequently during the warm seasons. Infection with EPEC is often severe and leads to a high mortality rate in developing countries. The symptoms of the disease include watery diarrhea, vomiting, and fever. All EPEC strains induce a characteristic attaching and effacing (A/E) lesion on the brush border of the intestine which can be mimicked in tissue culture (Fig. 34.2). Pedestal-like structures form beneath the intimately adhering bacteria, due to the polymerization of actin. The accumulation of actin beneath the bacteria can be detected by a fluorescent-actin staining (FAS) assay. In addition, EPEC adheres to epithelial cells in tissue culture in a localized pattern, which can be detected by light microscopy.

Intimate attachment of EPEC to epithelial cells is mediated by an adhesin called intimin, which is encoded by the *eae* gene located on a 35-kb pathogenicity island, called the locus of enterocyte effacement (LEE). The LEE also encodes a type III secretion system called Esc, several proteins secreted by this secretion system called EspA, B, D, and F, and Tir. Tir becomes localized to the host cell membrane, where it serves as a receptor for intimin. The formation of the A/E lesions requires the Esc proteins, EspA, B, D, Tir, and intimin. The mechanisms that lead to diarrhea are unknown but may be related to changes in ion secretion and intestinal barrier function that have been detected *in vitro* and/or to loss of microvilli.

Localized adherence of EPEC to epithelial cells is dependent on the presence of a 90-kb plasmid, which

FIGURE 34.2 Typical attaching/effacing (A/E) lesions caused by enteropathogenic *E. coli* (EPEC) in an intestinal epithelial tissue culture model. Bacteria adhere intimately to the epithelial cells and induce formation of pedestals in the cell membrane (courtesy of Barry McNamara).

carries the genes required for the biogenesis of type IV fimbriae, called bundle-forming pili (BFP). BFP form ropelike structures (Fig. 34.3) that are responsible for the aggregation of EPEC bacteria to each other and for the localized adherence of EPEC to host epithelial cells. In addition to BFP, some EPEC strains produce other types of fimbriae that may also contribute to localized adherence. Some EPEC strains also produce a low molecular heat stable toxin called EAST1, similar to EAST1 of enteroaggregative *E. coli*, but the importance of this toxin in disease is unknown.

C. Enterotoxigenic *E. coli*

Enterotoxigenic *E. coli* (ETEC) is a cause of infantile and childhood diarrhea in developing countries and travelers' diarrhea in adults of industrialized countries visiting ETEC-endemic areas. Infection in travelers results in mild watery diarrhea in the majority of cases, whereas in infants from endemic areas, it can cause more severe diarrhea. ETEC has a short incubation period of 14–50 h. Epidemiological studies indicate that ETEC infection is more common in warm seasons and is transmitted through fecally contaminated food and water. The infectious dose for ETEC is approximately 10^8 .

ETEC colonizes the mucosal epithelial cells of the small intestine and produces at least one of the two enterotoxins known as heat-labile toxin (LT) and heat-stable toxin (ST); both are encoded on a plasmid. LT is similar to cholera toxin (CT) in structure, function, and mode of action (see preceding). ST is a small

FIGURE 34.3 Bundle-forming pili produced by enteropathogenic *E. coli* (EPEC). Each bundle consists of several individual fimbrial filaments about 7 nm in diameter (reproduced with permission from Anantha *et al.*, (1998). *Infect. Immun.* 66, 122–131).

polypeptide that activates intestinal guanylate cyclase, leading to accumulation of GMP, secretion of chloride and water, and, thus, diarrhea. ST resembles a peptide, guanilyl, normally found in the intestinal epithelium.

ETEC strains produce multiple fimbriae that are host species-specific. Human ETEC fimbriae, called colonization factor antigens (CFAs), are associated with specific O serogroups. These fimbriae exhibit different morphological features, such as rigid rods similar to common fimbriae, bundle-forming flexible rods, and thin wavy filaments. In addition, many human ETEC strains produce a type IV fimbria, called Longus.

D. Enterohemorrhagic *E. coli*

Enterohemorrhagic *E. coli* (EHEC) is an emerging enteropathogen, which can cause watery diarrhea followed by bloody diarrhea, an illness designated hemorrhagic colitis (HC). EHEC is also associated with severe cases of hemolytic uremic syndrome (HUS), with a mortality rate of 5–10%. The reservoir for this organism is the intestinal tract of cattle and, therefore, undercooked contaminated beef is the major source of infection. Contaminated milk, juice, lettuce, sprouts, and fast food have also caused outbreaks. Since the infectious dose is as low as 50–200 organisms, it is not surprising that EHEC is also spread by direct person-to-person contact.

The most important EHEC serotype, O157:H7, has been the cause of several food-borne outbreaks in the United States, Canada, Japan, and Europe since the 1980s. The mortality related to HUS has brought public attention to EHEC infections and has been the impetus for new regulations for handling and cooking of beef products.

The major pathogenic feature of EHEC is production of the bacteriophage-encoded Shiga toxin (or verotoxin), that is closely related to the Shiga toxin of *S. dysenteriae*. HUS is thought to be the result of hematogenous dissemination of Shiga toxin, cytotoxicity to endothelial cells, and microscopic thrombosis in the kidneys and elsewhere. Shiga toxins are also essential for development of bloody diarrhea and hemorrhagic colitis. Many EHEC strains also produce EAST1 toxin, similar to the toxin of enteroaggregative *E. coli*.

Similar to EPEC, EHEC strains also possess the LEE pathogenicity island on the chromosome (see preceding) and exhibit classic A/E histopathology. The A/E phenomenon is thought to be responsible for development of watery diarrhea, in a manner similar to EPEC diarrhea.

E. Enteroaggregative *E. coli*

Enteroaggregative *E. coli* (EAEC) is a cause of persistent diarrhea in children of developing and developed countries. EAEC infects the small bowel and causes diarrhea in less than 8 h, which may persist for >14

days. The diarrhea is usually mucoid and may be watery, with low-grade fever. EAEC has also been associated with diarrhea in human immunodeficiency virus-infected patients. More importantly, colonization with EAEC is linked to growth retardation in children, independent of the symptoms of diarrhea.

EAEC induces the formation of a mucous biofilm, which can trap and may protect the bacteria, leading to persistent colonization and diarrhea. Bacteria also elicit a cytotoxic effect on the intestinal mucosa. The cytotoxic effect is mediated by genes present on a 100-kb plasmid.

EAEC exhibits an aggregative adherence phenotype, mediated in some strains by a flexible bundle-forming fimbria called Aggregative Adherence Fimbriae I (AAF/I). AAF/I is a member of the Dr family of adhesins, present in uropathogenic *E. coli*.

EAEC strains also produce a ST-like toxin, EAST1, which is linked to the AAF/1 gene cluster on the 100-kb plasmid. The role of EAST1 in diarrhea is unknown. In addition, EAEC strains produce a 108-kDa cytotoxin that belongs to the autotransporter family of proteins. This protein also exhibits enterotoxin activity.

F. *Bacillus cereus*

Bacillus cereus is a gram-positive spore-forming rod that resides in water, soil, and as part of the normal flora in humans. This organism produces several toxins and causes two forms of toxin-mediated food poisoning, one characterized by emesis and the other by diarrhea. The production of either the emesis or diarrheal toxin is dependent on the type of the food on which the bacteria grow. The emetic toxin is a small toxin that is resistant to heat, extreme pH, and proteolytic enzymes. The toxin acts on the enteric nervous system through unknown mechanisms. The emetic toxin is associated with fried rice in the majority of cases. The emetic form of the disease has an incubation period of 2–3 h and elicits symptoms of vomiting and abdominal cramps that last 8–10 h.

The diarrheal toxin is a secretory cytotoxin consisting of a two- to three-component protein complex. This toxin induces secretion in the rabbit-ligated ileal loop and is cytotoxic in tissue culture. The mechanism of action of this toxin is unknown. The diarrheal toxin is associated with a variety of foods, such as sausage, vanilla sauce, and puddings. The incubation period for the diarrheal form ranges from 6 to 14 h. The illness is characterized by diarrhea and abdominal cramps, which may last 20–36 h.

G. *Staphylococcus aureus*

Staphylococcus aureus is a gram-positive coccus that is among the most common causes of bacterial food-borne disease. Food poisoning usually occurs by contamination of food with infected wounds on the hands, from the normal flora of skin or from the respiratory tract of food handlers. Foods such as ham and custard, which have a high concentration of salt or sugar, provide a good growth medium for *S. aureus*. One to 6 h after ingestion of the contaminated food, the symptoms of food poisoning begin, with severe vomiting and abdominal pain followed by diarrhea, which may last 24–48 h.

Food poisoning with *S. aureus* results from ingestion of the small enterotoxins A, B, C, D, or E, which are superantigens. Enterotoxin A is the most common one associated with food poisoning. These toxins act on enteric nervous system through unknown mechanisms. As little as 100–200 ng of the toxins can cause food poisoning. The *S. aureus* toxins are resistant to heat, irradiation, pH extremes, and proteolytic enzymes. Therefore, even overcooking of the contaminated food does not prevent the food poisoning. Involvement of *S. aureus* in outbreaks of food-borne disease is confirmed by detection of enterotoxins in food and by phage typing.

H. *Clostridium perfringens*

Clostridium perfringens is a gram-positive spore-forming organism that can tolerate aerobic conditions, unlike other members of Clostridia. *C. perfringens* type A exists in soil and in the intestinal tracts of most animals. This organism can cause a relatively mild food poisoning, more frequently in winter. Diarrhea and abdominal cramps develop 6–24 h following ingestion of preformed toxin and last up to 24 h. Toxigenic strains of *C. perfringens* usually grow on foods such as meat and poultry at temperatures between 15 and 50°C, with a doubling time as short as 10 min. The spores are heat-resistant and can survive cooking and germinate after cooling. *C. perfringens* type A produces a 35-kDa cytotoxin called *C. perfringens* enterotoxin (CPE) during sporulation. CPE binds irreversibly to cells and forms ion-permeable channels in intestinal epithelial cells and acts as a superantigen that reacts with human T cells.

Clostridium perfringens can also cause non-food-poisoning diarrhea. The diarrhea is more severe, with blood and mucus in feces, and lasts longer. The disease occurs predominantly in the elderly or results from antibiotic therapy, similar to the cases with *C. difficile*.

Infections with *C. perfringens* type C can lead to necrotizing enteritis known as “pig-bel,” a syndrome

described in New Guinea related to consumption of large undercooked pork meals in native feasts. The symptoms of pig-bel include severe abdominal pain, bloody diarrhea, vomiting, and death due to intestinal perforation. The symptoms of pig-bel are associated with a toxin called β toxin. β Toxin is a cytotoxin with an unknown mechanism of action. This toxin is usually inactivated by proteolytic enzymes in the intestine. However, lack of proteolytic enzymes in malnourished hosts or inhibition of these enzymes by certain foods, such as sweet potato, allows the activity of β toxin and subsequent necrotizing enteritis.

III. BACTERIAL AGENTS OF ENTERIC FEVER

A. *Salmonella typhi*

Typhoid fever is a severe systemic disease caused by *S. typhi*. The disease is characterized by fever and abdominal symptoms. Infection can be transmitted by consumption of water or food contaminated with the feces of a patient or a chronic carrier. Humans are the only known reservoir for this organism, making the studies of typhoid infection difficult. However, *S. typhimurium*, which normally causes gastroenteritis in humans, causes a disease similar to typhoid in mice. Therefore, most of the studies of typhoid have focused on infection of mice and mouse macrophages with *S. typhimurium*. However, it is not clear that all of the conclusions from studies of *S. typhimurium* in mice apply to *S. typhi* in humans.

Following oral inoculation in mice, *S. typhimurium* survives the gastric acid barrier and reaches M cells, specialized epithelial cells that cover lymphoid tissues of the small intestine. Bacteria use M cells to penetrate the intestinal mucosa, whereupon they are engulfed by macrophages. Within macrophages, *Salmonella* attenuates the acidification process and multiplies. Survival within macrophages results in spread of the organisms and systemic infection. Bacteria enter the blood through the thoracic duct. Finally, bacteria are taken up by tissue macrophages in the bone marrow, liver and spleen.

The ability to multiply in macrophages and cause systemic infections is encoded by genes that reside on a second pathogenicity island, SPI-2, at 30 min on the *S. typhimurium* chromosome. (See preceding section on nontyphoidal *Salmonella* about SPI-I.) In addition to the products of these genes, intramacrophage survival is also modulated by the PhoP/PhoQ two-component regulatory system. These proteins regulate acid phosphatase synthesis and unknown genes,

which are essential for survival in the acidic environment of the macrophage.

B. *Yersinia* spp.

Within the genus *Yersinia*, *Y. pestis*, *Y. pseudotuberculosis*, and *Y. enterocolitica* are pathogenic for humans. Based on DNA hybridization techniques, *Y. enterocolitica* has recently been subdivided into eight other species. *Y. pestis* is the cause of bubonic plague, the "Black Death," which claimed one-fourth of Europe's population in the fourteenth century. *Y. pseudotuberculosis* and *Y. enterocolitica* are the causes of yersiniosis, a disease more prevalent in developed countries. Yersiniosis is characterized by an enteric feverlike illness, which is accompanied by acute diarrhea. Mesenteric adenitis is a common manifestation of the disease, which causes an acute appendicitis-like syndrome, with fever and abdominal pain. Extra-intestinal manifestations can also include septicemia and nonpurulent arthritis.

Infections with *Y. pseudotuberculosis* are more common in animals and less frequent in humans. *Y. enterocolitica* is carried by healthy pigs but is pathogenic for humans. It is transmitted by ingestion of contaminated water or food, more commonly, contaminated milk. The organisms can multiply at low temperatures, such as those of refrigerated food. The infectious inoculum may be 10^9 organisms and the incubation period may last 4–7 days.

Following ingestion of *Yersinia*, bacteria adhere to and enter the intestinal epithelial cells. Infection then spreads to the mesenteric lymph nodes, where abscesses develop. Adherence of *Yersinia* to host cells is mediated by a plasmid-encoded adhesin, called YadA, and a chromosomally encoded protein, called Invasin. Invasin mediates entry into cells by interacting with $\beta 1$ integrin receptors. This interaction leads to the extension of a pseudopod that forms a "zipper" around the bacterium, resulting in internalization.

At 37°C under low calcium conditions *in vitro*, *Yersinia* spp. secrete a set of proteins called Yops. Yops are virulence factors that enable bacteria to survive and multiply within lymphoid tissues of the host. The genes encoding Yops reside on a 70-kb virulence plasmid. Yops are secreted by a type III secretion system called Ysc and the secretion is regulated by temperature and contact with eukaryotic cells. Upon contact of bacteria with host cells, Yops are synthesized, secreted, and some are injected into the cytoplasm of host cells. Following injection, YopE and YopT act as cytotoxins that disrupt the actin microfilament structure. YopH is a protein tyrosine phosphatase that dephosphorylates certain proteins of macrophages. These Yops together inhibit phagocytosis by macrophages. YopP (YopJ)

induces apoptosis of macrophages, which results in release of proinflammatory cytokines and subsequent inflammatory responses to infection.

Yersinia enterocolitica also produces an enterotoxin similar to heat-stable toxin of *E. coli*, called Yst. This enterotoxin might be responsible for cases of food poisoning caused by this organism.

IV. BACTERIAL AGENTS OF GASTRITIS

A. *Helicobacter pylori*

Helicobacter pylori is a spiral, microaerophilic gram-negative bacterium with two to six polar sheathed flagellae that endow the bacterium with a corkscrew mode of motility. It has a relatively small genome of 1.7×10^6 bp which is highly AT-rich, similar to that of Campylobacters. The complete sequence of the genome has been determined for two strains. This organism is extremely prevalent, residing in large numbers (10^8 – 10^{10} organisms per stomach) in the stomachs of at least half of the human population. *H. pylori* probably is not found in the environment or in animals and, therefore, person-to-person contact and the fecal-oral route are the likely means of transmission. Once inoculated, the incubation period is estimated to be 3–7 days and infection can last for the lifetime of the host. *H. pylori* exhibits tissue specificity exclusively for gastric mucosal epithelial cells and does not invade beyond these tissues. Detection of the organisms is best accomplished by biopsy of stomach tissue and subsequent testing for urease activity, by serologic testing, or by culture.

Infections with *H. pylori* result in acute and chronic gastric inflammation, which, when untreated, can lead to peptic ulcers or stomach carcinoma. The majority of cases of gastric and duodenal ulcers are caused by *H. pylori*. The outcome of infection with *H. pylori* depends on a variety of bacterial, host, and environmental factors.

Gastric inflammation by *H. pylori* is mediated by several virulence factors. All *H. pylori* strains produce urease in very high amounts. Urease is a nickel-containing hexameric enzyme, which catalyzes hydrolysis of urea to ammonia. Ammonia neutralizes gastric acid of the stomach, allowing the organism to colonize. Flagellae are another important colonization factor of this organism, allowing the bacteria to move along the mucous layer of the stomach. Most *H. pylori* strains produce a vacuolating cytotoxin, called VacA, which is an autotransporter protein. This cytotoxin induces acidic vacuoles in the cytoplasm of eukaryotic cells. Also, the *H. pylori* strains that are more associated

with duodenal ulcer and stomach cancer carry the cytotoxin-associated gene (*cag*) pathogenicity island. Genes on the *cag* PI are required for secretion of IL-8 and tyrosine phosphorylation of host proteins.

V. MISCELLANEOUS BACTERIAL ENTERIC PATHOGENS

Thorough coverage of all enteric bacterial pathogens is beyond the scope of this article. However, we briefly describe a few other common enteropathogenic bacteria in the following section:

A. Non-cholerae vibrios

Vibrios parahaemolyticus, *V. vulnificus*, *V. mimicus*, *V. fluvialis*, *V. furnissii*, and *V. hollisae* reside in aquatic environments and prefer high salt and warm temperature habitats. These organisms have been implicated in intestinal infections following consumption of contaminated raw or undercooked shellfish. *V. parahaemolyticus* and *V. vulnificus* can also cause wound infections and septicemia. *V. parahaemolyticus* produces the thermostable direct hemolysin (TDH), which acts as an enterotoxin to stimulate intestinal secretion and subsequent diarrhea. Hemolysin may also be involved in tissue damage observed in wound infection. This hemolysin elicits the Kanagawa phenomenon on Wagatsuma agar, a phenotype specific to pathogenic strains.

Vibrios vulnificus is an invasive pathogen. Eating contaminated raw oysters leads to septicemia 24–48 h later, particularly in people with underlying liver disease. This organism produces several proteolytic enzymes and a hemolysin, which contribute to overt damage to epithelial cells in wound infections. *V. vulnificus* also produces a capsule, which has been associated with virulence.

B. *Aeromonas* spp.

Aeromonas spp. are widely distributed in marine environments and can be transmitted to humans via contaminated food, especially during summer. Three species, *A. hydrophila*, *A. sobria*, and *A. caviae*, cause diarrhea in humans. *A. hydrophila* produces a hemolysin called aerolysin or β -hemolysin, which, in addition to cytolytic activity, acts as an enterotoxin and induces diarrhea. It also produces other enterotoxins and cytoskeleton-altering toxins. In addition, *A. hydrophila* produces a type IV fimbria that might contribute to virulence.

C. *Plesiomonas shigelloides*

Plesiomonas shigelloides has biochemical similarities to *Aeromonas* and antigenic similarities to *Shigella* spp. It is primarily a marine microorganism, which can be transmitted to humans by raw or undercooked seafood. Diarrhea, accompanied with relatively severe abdominal cramps, occurs 24 h after ingestion of the organism. The stool may contain mucus, blood, and pus, suggesting an invasive mechanism of the disease. *P. shigelloides* produces a heat-labile enterotoxin with cytoskeleton-altering activity and a heat-stable enterotoxin with unknown mechanism of action.

Plesiomonas shigelloides also causes extraintestinal infections, such as meningitis in neonates, septicemia in immunocompromised hosts, and septic arthritis.

D. *Listeria monocytogenes*

Listeria monocytogenes is the only species of *Listeria* that is pathogenic to humans. This organism is a gram-positive rod, which is present in soil, as part of the fecal flora of many animals, and on many foods, such as raw vegetables, raw milk, cheese, fish, meat, and poultry. Diarrhea can occur following ingestion of 10^9 organisms via contaminated food. The incubation period is long and can last between 11 and 70 days. Infections with *L. monocytogenes* are uncommon in the normal population, but in immunocompromised patients, neonates, the elderly, and pregnant women, infection can lead to encephalitis, meningitis, and stillbirth.

Listeria monocytogenes invades both epithelial cells and phagocytes. Entry involves a “zippering” mechanism, similar to that described for *Yersinia* entry (see preceding). Interaction between Internalin, a bacterial protein, and E-cadherin, a receptor on epithelial cells, induces phagocytosis. Once inside the phagocytic vacuole, bacteria lyse the vacuolar membrane by a hemolysin called listeriolysin O and spread within the cytoplasm. In the cytoplasm, a bacterial protein called ActA induces assembly of actin microfilaments behind the bacterium, which results in movement of bacteria in a manner similar to movement of *Shigella* inside the cytoplasm (see preceding). Bacteria move to adjacent cells and spread. Genes involved in escape from the vacuole and in intra/intercellular spread are carried on a pathogenicity island in the *L. monocytogenes* chromosome.

E. Enterotoxigenic *Bacteroides fragilis*

Bacteroides fragilis is a gram-negative non-spore-forming anaerobic rod that comprises a part of the normal intestinal flora of nearly all humans.

Enterotoxigenic *B. fragilis* (ETBG) strains produce a toxin that stimulates fluid secretion in the intestinal lumen and causes rounding of epithelial cells and loss of intestinal microvilli in an *in vivo* intestinal model. These strains have been linked to diarrhea in animals and in a small number of studies of humans.

F. *Clostridium botulinum*

Clostridium botulinum is the cause of food poisoning, which can occur by ingestion of preformed toxins in inadequately processed food, such as home-canned vegetables and fish. Vomiting and diarrhea occur before neurological symptoms begin. The disease is caused by neurotoxins A, B, or E. Infant botulinum is another manifestation, which is different from food poisoning in that toxins are produced after germination of spores in gut. *Clostridium botulinum* also produces a cytotoxin called C2 toxin, which can alter the cell cytoskeleton by ADP-ribosylation of G actin and preventing polymerization of G to F actin. The role of this toxin in disease is unknown.

ACKNOWLEDGMENTS

Escherichia coli and *Salmonella*, Genetics

K. Brooks Low

Yale University

GLOSSARY

bacteriophage (*phage*) A virus that infects bacteria. Lysogenic bacteriophages sometimes insert stably into the chromosome without replicating. Lytic bacteriophages always replicate following infection, and usually kill their host bacterial cell as they produce a burst of progeny phage particles.

conjugation A process of DNA transfer between bacterial cells involving cell-to-cell contact and requiring the functions of fertility factor genes in the donor cell.

curing The elimination of a replicon such as a plasmid or prophage from a bacterial strain.

F-prime A plasmid derived by excision from a chromosomally integrated fertility factor (F), so that it carries a portion of the main chromosome, thus enabling a partial diploid (merodiploid) state.

fimbriae Hairlike proteinaceous appendages (100–1000 per cell), 2–8 nm in diameter, on the surface of bacteria that are often involved in adhesion to specific types of eukaryotic cells.

flagella Thin helical appendages on the surface of bacteria (5–10 per cell; originating at random points on the surface—peritrichous), about 20 nm in diameter, that can rotate and cause the cell to swim.

genome The total stably inherited genetic content of a cell, including chromosome and plasmids.

genotype The particular nucleotide sequence of the genome of a particular strain. A genotypic symbol

(e.g., *leuB44*, a mutation in a leucine biosynthetic gene) is used to notate any change from the wild type (*leu*⁺).

horizontal gene transfer The introduction of new genetic material into a cell's genome as a result of uptake from an outside source such as by mating (conjugation), transduction or transformation (i.e. not simply by mutation and vertical inheritance into vegetative descendants); usually used to denote gene transfer between somewhat unrelated species.

lysogenic conversion (*phage conversion*) A change in bacterial phenotype due to either phage infection or stable establishment (lysogeny) of a bacteriophage in the genome, whereby new (bacteriophage) genes are expressed, such as genes for toxin production or a new cell surface antigen.

mutation Any inherited change in nucleotide sequence in the genome.

operon A set of contiguous genes that are transcribed together into a single mRNA, together with any *cis*-acting regulatory sequences. The gene products are thus controlled coordinately. If two or more genes are controlled coordinately, but are at separate sites on the genome, they constitute a regulon.

palindrome An inverted repeated sequence. In double-stranded DNA, the ends of a palindrome are self-complementary, and can melt and reanneal to form hairpin-like structures.

pathogenicity island A cluster of contiguous genes in a genome that appear to originate from a distant

evolutionary source and that is involved in conferring a pathogenic phenotype to a strain.

phase variation A reversible change in cell surface antigens, controlled by a genetic switch in the genome.

phenotype The observable characteristics of an organism based on its cellular or colonial morphology, biochemical structure, growth characteristics, or serological specificity. A phenotypic symbol (e.g. Leu⁻, denoting a growth requirement for leucine) is used to indicate any change from the wild type (Leu⁺).

plasmid An independently replicating component of the genome, usually much smaller than the main chromosome and usually not essential for cell survival.

recombination, genetic The interaction of nucleic acid elements of the genome to produce a new arrangement of base pairs; sometimes also including the addition from an outside source of new independently replicating elements such as plasmids, thus enlarging the genome.

R-prime A plasmid derived by excision from a chromosomally integrated R factor, so that it carries a portion of the main chromosome, thus enabling a partial diploid (merodiploid) state.

serotype (*serovar*; *bioserotype*; *ser*) A strain-specific immunological reactivity due to particular antigenic components on or near the cell surface of a particular strain.

transduction A gene transfer involving the injection of genetic material carried in a bacteriophage capsid.

transformation, bacterial A gene transfer by uptake of naked DNA into a cell.

Over 2300 Wild-type (naturally occurring) varieties of *Salmonella* are known to inhabit Earth and an estimated vast excess of over 10,000 (perhaps more than 100,000) wild-type varieties of *Escherichia coli* exist as well. To help explain this striking diversity, there is overwhelming evidence that a complex spectrum of vertically inherited mutational events and horizontal gene transfer events has taken place over the course of evolution, since the time these two species diverged from a common ancestor approximately 150 million year ago. The resulting population of genetic variants includes mostly innocuous inhabitants of avian, human, and other animal intestinal tracts (*E. coli* cells normally constitute about 1% of the bacterial flora in the human intestine), and also a large number of highly pathogenic variants that are able to invade the intestine, blood, and other organs, exacting a huge toll in terms of disease and death (there are 3.6 million deaths annually from *Salmonella* infections worldwide) and the associated economic burden (over a billion dollars annually in the United States alone). As is well known, certain

strains of *E. coli* and *Salmonella* have been used since the 1940s to serve as laboratory workhorses for studies of mutation, physiology, gene transfer, and fundamental life processes such as mechanisms of genetic inheritance, macromolecular synthesis, biosynthetic pathways, and gene regulation. The huge families of laboratory-derived strains and seminal findings from these experiments is a crucial counterpart to the lives of *E. coli* and *Salmonella* in the wild. The genetics of these organisms is based on the study of their genomic structure and mechanisms of variation observed both in the laboratory and in nature.

I. TAXONOMIC NICHE OF ESCHERICHIA COLI AND SALMONELLA

The description of the phylogeny of *Escherichia coli* and *Salmonella* has had a particularly tortuous and confusing history. This is in part because of the medical relevance of the many pathogenic varieties of these strains and the ensuing detail of study, and in part due to the intrinsically vast spectrum of subtle antigenic variations that have evolved on the surface of these cells, and, furthermore, the ability of the cells of even one strain to alternate between antigenic types in their normal course of growth.

The larger family of bacterial genera to which *E. coli* and *Salmonella* belong is the Enterobacteriaceae (or Enterobacteria), defined in 1937 by Rahn, which has diverse natural habitats including animal intestines, as well as plants, soil, and water. The number of genera, let alone species, defined to be in this family has varied repeatedly for almost 100 years, depending on available diagnostic measures and criteria of relatedness agreed to and disagreed to by many investigators. For example, the number of genera of Enterobacteriaceae listed in *Bergey's Manual of Determinative Bacteriology*, 5th edition (1939), a widely used standard, is nine, with 67 species (not including *Salmonella*, whose taxonomic history has varied widely depending on the concept of species), whereas the 8th edition (1974) lists 12 genera and 37 species. As of the 1990s, the use of methods of DNA-DNA hybridization to determine relatedness has led to the clear resolution of over 30 genera and 100 species within the "extended" family of Enterobacteriaceae.

Within this family, certain genera such as *E. coli* and *Shigella* are very closely related (70–100% homologous); yet they are maintained in separate genera because of the practical difference in clinical diseases they cause. The next closest relatives of *E. coli* are the *Salmonella* and *Citrobacter* genera, then *Klebsiella* and *Enterobacter*. More distantly related genera include

Erwinia, *Hafnia*, *Serratia*, *Morganella*, *Edwardsiella*, *Yersinia*, *Providencia* and, most distantly, *Proteus*.

The above genera were all known before 1965 (starting with *Serratia* in 1823), mostly as a result of infection in and the fecal content of humans or animals. Since the late 1970s, 17 more genera in this family have been discovered, some from clinical origin and some from water, plants, or insects.

The major characteristics that serve to identify the Enterobacteriaceae are that they are gram-negative rod-shaped bacteria that, with minor exceptions, can grow aerobically and anaerobically, produce a catalase but not oxidase, ferment glucose and convert nitrates to nitrites, contain a common enterobacterial antigen, are usually motile by means of flagella, do not require sodium for growth, and are not spore-forming. Further subclassification depends on other subtleties in metabolic capacities, such as the ability to use various sugars. For practical reasons, many medically important strains are diagnosed also with antisera specific to components of the outer membrane. Horizontal gene transfer is believed to occur between virtually all members of the family.

E. coli was discovered in feces from breastfed infants by Theodor Escherich, in 1885, and was first named *Bacterium coli*. By the early 1900s it became clear that it differed from another similar organism known primarily as a pathogen, *Bacillus typhi* (known since 1930 as *Salmonella typhi*), and hence was renamed *Escherichia* in honor of its discoverer. *E. coli* was found to ferment lactose, whereas the (*Salmonella*) *typhi* strains could not. In hindsight, this ability to ferment lactose and the divergence of *E. coli* and *Salmonella* roughly 150 million years ago coincides rather strikingly with the assumed appearance of mammals, and the assumed first synthesis of lactose in nature, at about the same evolutionary time. The differing abilities of *E. coli* and *Salmonella* to ferment lactose, and invade mammals in a pathogenic fashion suggests a rapid adaptation to the newly emerging families of mammals on Earth.

In contrast to the discovery of *E. coli* as a common and compatible inhabitant of the human intestine, *Salmonella*, named in 1900 after Salmon, was first defined as the causative agent for hog cholera (hence the initial strain name, "choleraesuis"). Investigations of the varied and varying antigenic properties of many similar strains from diseased animals and humans led to a classification scheme (Kauffmann-White) based on three types of antigens. Further classification was based on differences in sensitivity to various bacteriophages.

The three broad classes of antigens used to categorize both *E. coli* and *Salmonella* isolates are based on

three types of surface structures. The outermost are the flagella that are present in motile strains. The antigens of flagella are termed H antigens (Hauch, meaning "cloud" or "film," describing colonies of motile bacteria). Next is the group of outermost surface layers including the capsule (in some strains), envelope and fimbriae. The antigens of this group are called K (for Kapsule). Internal to the K group is a group of antigens associated with the phospholipids in the outer membrane—termed O antigens because strains that lose their motility (and are thus "ohne Hauch," that is, without cloud or film as colonies) through loss of flagella can expose the lower-lying (O) antigens. What makes this overall system feasible is that by selective treatment the outer antigens can be removed or inactivated stepwise by alcohol (for the H antigen, i.e., the flagella) and by heating to 100°C for 2 h (which inactivates most or all of the K antigens), which thus leaves material containing only the O antigens. By preparing antibodies to the bacteria in all three states, the antisera can be subtractively purified to obtain fractions specific for each of the three antigen classes.

The results of decades of effort in this direction in the early 1900s (and continuing into the present, for more specific isolates) resulted in a well-defined spectrum of antigenic determinants that define a multitude of *E. coli* and *Salmonella* strains. In *E. coli* at least 173 distinct O antigens, 80 K antigens, and 56 H antigens are known. Although it is not likely that all conceivable combinations exist in nature, it is thought that well over 10,000 variants exist, more than for any other species. Note that the common laboratory strain, *E. coli* K-12 (also written K12 or K₁₂), does not show any K or O antigenic determinants. The name K-12 was applied in a Stanford clinic where it was isolated in 1922, long before the K, O, H system was developed.

As for *E. coli*, *Salmonella* strains from natural sources display a huge variety in O and H (and sometimes K) antigenic determinants, and over 2300 combinations have now been registered, second only to *E. coli* in complexity. Some of this complexity is due to the ability of *Salmonella* to present more than one form of H antigen (phase variation). Additional variation is introduced by the phenomenon of lysogenic conversion, whereby certain bacteriophages infect a strain, become lysogenized as a stable prophage, and express one or more new genes that alter the O surface antigens. Until the early 1940s, the names used for different isolates were taken to mean separate species, thus hundreds of *Salmonella* species are described in the early literature. In 1973, a major simplification occurred as a result of DNA-relatedness studies of

Crosa and colleagues, who found that virtually all *Salmonella* strains are closely related and can be considered a single species, divided into six subgenera (subspecies). Officially, this species is named *Salmonella choleraesuis*; however a subsequent proposal is pending to name the species *Salmonella enterica* and thus use a name not associated with any of the earlier isolates. Many investigators are already using this terminology, wherein the particular strain is defined with a serovar name that corresponds in most cases with the older "species" name, that is, *Salmonella enterica* serovar Typhimurium, or simply *Salmonella* Typhimurium.

II. THE GENOME

A. The chromosome

The genomes of *E. coli* and *Salmonella* strains consist of a single major circular chromosome of over 4 Mb of DNA (the genomes from natural isolates of *E. coli* range in size from 4.5–5.5 Mb), and commonly one or more small independently replicating (extrachromosomal) DNA plasmids, usually 100 kb or less. Thus, these organisms are haploid, although a second copy of a portion of the chromosome can be carried on a plasmid, thus creating a partial diploid (merodiploid) state. Strains of this type have been used extensively in the laboratory in genetic studies of dominance and regulation.

Though the genome is haploid, the number of copies of the main chromosome varies, ranging between approximately one per cell in the resting (stationary phase) state to sometimes four per cell in rapidly dividing cells in rich growth media. In this state there are more than one set of replication growth forks along the chromosome, which replicates divergently beginning at a site called the origin (of replication) and ending in a region called the terminus (see Fig. 35.1). Thus, in rapidly growing cultures there are at any given time more copies of genes located near the origin than near the terminus. As a result of this multiplicity of growth forks, rapidly growing cells divide and produce two daughter cells as often as every 20 min, even though the time required for any one growth fork to move from the origin to the terminus is 40 min. Genes whose products are used in high concentration during rapid growth (such as genes for components of the ribosome) tend to be located nearer the origin than the terminus, thus allowing relatively high amounts of product formation.

The chromosomes of *E. coli* and *Salmonella* are clearly related, as can be seen from Fig. 35.1, which shows the general congruence of the sequence of genes around the chromosomes for the two most commonly used laboratory strains (originally isolated from the wild), *E. coli* K-12 and *Salmonella* Typhimurium LT2. The vast majority of the genes in *E. coli* K-12 have counterparts at the corresponding regions of the *Salmonella* Typhimurium chromosome, and vice versa. At the base-sequence level, the DNA homology varies from approximately 75–99% for various protein-coding genes. The G + C to A + T DNA base ratios are also similar (50.8% G + C content for *E. coli* K-12; 52% for *Salmonella* Typhimurium). Recombination can occur between the *E. coli* and *Salmonella* chromosomes, albeit rarely (see later discussion), to form viable hybrid strains that carry portions from each chromosome, and most of the gene functions from one organism can substitute for the analogous function in the other.

Superimposed on the general congruence of these two related genomes are a number of sites in which an insertion or deletion shows a distinct difference between the two, as indicated in Fig. 35.1 (and see later discussion). Figure 35.1 also shows a region of the chromosome, in the 26–40 min region, where a large inversion has reversed the gene sequence in *E. coli* K-12 relative to *Salmonella* Typhimurium. It is believed that the *Salmonella* Typhimurium configuration of this region is the more distantly ancestral one because certain other types of Enterobacteria related to *E. coli* and *Salmonella* typhimurium carry inversions analogous to the 26–40 min inversion but differing greatly in extent, ranging from a much smaller inversion (in *Klebsiella aerogenes*) to a much larger inversion (in *Salmonella* Enteritidis). Thus, it is believed that over the course of evolution a number of independent inversion events in this region occurred, starting from a configuration similar to that of *Salmonella* Typhimurium.

A summary of types of genes and other genetic elements on the *E. coli* K-12 chromosome is listed in Table 35.1. For structural genes that encode proteins, Table 35.2 indicates the major classes based on broad functional role in the cell.

B. Extrachromosomal elements

Most natural isolates of *Salmonella*, and many of *E. coli*, carry extrachromosomal plasmids. These are broadly classified as either self-transmissible (conjugative) or not (nonconjugative). Conjugative plasmids carry a number of genes needed for conjugative DNA transfer between cells (see later discussion). Some nonconjugative plasmids can be conjugationally transferred (mobilized) when a conjugative plasmid is also

TABLE 35.1 *Escherichia coli* K-12 genome, major features^a

Elements	Number	Characteristics
Base pairs	4,639,221	Single circular chromosome
Replichores	2	Divergently replicating halves, from single origin to terminus region
G + C content	50.8%	Overabundance of G in leading replicative strands (G ~26.2%; C, A, T ~24.6%)
Protein-codable genes	4288	88% of genome; 55% transcribed in direction of replication
average size (amino acids)	317	
number with 1000–2383 amino acids	56	
number with < 100 amino acids	381	
operons (known and predicted)	2584	73% single gene (predicted), 17% two genes, 10% three or more genes; 68% single promoter (predicted), 20% two promoters, 12% three or more promoters; > 10% regulated by more than one protein
Stable RNA genes		
rRNA	7 operons	All operons transcribed in replication direction; 5 CW, 2 CCW; location biased toward origin of replication.
tRNA	86	43 operons of various sizes widely dispersed in location and orientation.
Cryptic prophages	8	All located in late-replicating halves of replichores
other phage-like remnants	33	
Integration sites (att) for various lysogenic phages	>15	Widely dispersed around genome; sites for lambda-related phages located in late replicating portions of replichores
Insertion sequences	42	Number of repeats: 1 to 11; 4 classes (gene arrangements); size range 768–1426 bp
Insertion sites for fertility factors, (F, Col V, etc.)	>20	Some are at IS sequences
Repeated sequences (or, pseudo-repeated) Chi (GCTGGTGG)	761	RecBCD-mediated recombination initiator; highly skewed (~2:1) to leading replicative strand; widely distributed
Rhs	5	5.7–9.6 kb; components and G + C content variable; function unknown; not found in most other <i>E. coli</i> strains or in <i>Salmonella</i>
REP	697	~40-bp palindromes; sometimes tandemly repeated (1–12 copies) in 355 BIME sites; possible role in mRNA stabilization, gene expression and/or replication
IRU	19	Imperfect palindromes; size ~125 bp; function unknown
RSA	6	Imperfect palindromes; size ~152 bp; function unknown
Box C	33	High G + C; size ~56 bp; function unknown
iap	23	29-bp imperfect palindromes clustered near <i>iap</i> gene on the chromosome; function unknown

^aStrain K-12 MG1655. Abbreviations: BIME, bacterial interdispersed mosaic elements; CCW, counter-clockwise; CW, clockwise; IRU, intergenic repeat units (ERIC, enterobacterial repetitive intergenic consensus); REP, repetitive extragenic palindromic unit (PU, palindromic unit); Rhs, rearrangement hot spot.

TABLE 35.2 Distribution of major functional classes of *E. coli* protein-coding genes^a

Functional class	Number of genes	Percent of total
DNA replication, repair, recombination	115	2.7
Nucleotide metabolism	58	1.4
RNA metabolism, transcription	55	1.3
Protein synthesis	182	4.2
Amino acid metabolism	131	3.0
Cell membranes and structure	237	5.5
Fatty-acid and lipid metabolism	48	1.1
Binding and transport	427	10.0
Carbon-compound catabolism	130	3.0
Intermediary metabolism	188	4.4
Energy metabolism	243	5.7
Regulation	178	4.2
Phage, transposons	87	2.0
Miscellaneous	577	13.5
Unknown	1632	38.0
Total	4288

present to provide the necessary gene functions. Plasmids can be classified into groups based on whether they can coexist stably in the same cell. (Two different plasmids that can coexist are defined to different incompatibility, Inc, groups.) There are more than 30 Inc groups among the Enterobacterial plasmids.

About two-thirds of natural *Salmonella* Typhimurium strains carry a conjugative plasmid roughly 90 kb in size, similar to pSLT, which is present in strain LT2 as indicated in Fig. 35.1. These plasmids usually carry some of the genes that contribute to the virulence of *Salmonella* as a pathogen. Some wild-type *E. coli* strains (roughly 10% or more) also carry conjugative plasmids. The one denoted F from *E. coli* K-12 is about 100 kb in size and is unusual in that it is self-transmissible at very high frequency (see later discussion). The F factor and other F-like factors from *E. coli* strains have a number of genes involved in conjugation that are homologous to pSLT and similar plasmids from *Salmonella* Typhimurium strains.

Another type of plasmid, found in about 30% of wild-type *E. coli* strains, is the colicin factor. Colicins are toxins produced by one bacterium to kill or inhibit another bacterium. At least 20 distinct types of colicin factor, some of which are self-transmissible, have been found in *E. coli*.

III. WAYS IN WHICH THE GENOME CAN CHANGE

A. Mutation

Various changes in base sequence occur spontaneously at the rate of approximately 6×10^{-10} per base pair per generation (i.e. about 0.003 per genome) during vegetative growth. Much higher rates of mutagenesis are caused by mutagenic agents such as irradiation or exposure to certain chemicals, or even by simple prolonged starvation, as may occur in nature. The consequences of mutation can range from almost no effect (silent mutations, e.g. a base substitution in an amino acid-coding triplet in which the encoded amino acid does not change; however the change in tRNA used can lead to subtle changes in translation efficiency) to mild phenotypic changes (e.g. temperature sensitivity or leaky requirement for a growth factor; i.e. a leaky auxotroph or bradytroph, due to point mutations that alter just one or a few amino acids) to severe phenotypic changes (e.g. the inactivation of one or more genes due to deletions, frameshift mutations, or nonsense mutations). Sometimes a single mutation can result in a change in more than one phenotype or a change in production of a number of gene products, in which case the mutation is called pleiotropic. A broad range of phenotypes can be observed in *E. coli* or *Salmonella* mutants, listed in Table 35.3.

TABLE 35.3 Classes of phenotypic characteristics of mutant strains

Phenotypic class	Examples
Morphological	Colony size, texture, color; cell shape, motility, staining properties
Physiological	Dependence on temperature, oxygen, pH
Nutritional	Requirements for growth; possible carbon and energy sources
Biochemical	Breakdown products (e.g. acid) from carbohydrates, nitrates
Inhibition	Sensitivity to antibiotics, dyes, etc.
Serological	Agglutination by specific antisera
Pathogenic	Invasion capacity; virulence in variety of hosts

B. Recombination

Three distinct types of rearrangements of genetic elements (i.e. recombination) are observed throughout the living world: homologous, site-specific, and transpositional. Figure 35.2 shows diagrammatically the main topological features of these classes.

1. Homologous recombination

This refers to the interaction of two very similar DNA molecules (i.e. having almost the same base sequence

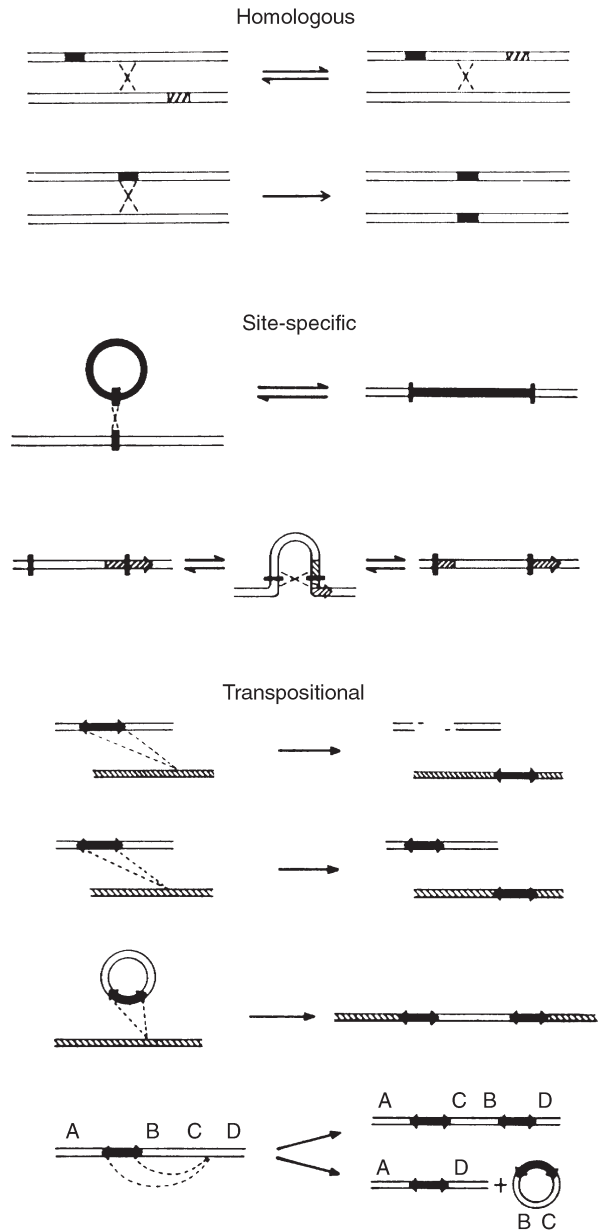

FIGURE 35.2 Schematic representation of major classes of genetic recombination. Adapted from Low, B. in Low, B. (ed.) (1988). *The Recombination of Genetic Material*. Academic press, pp. 6-7, with permission from the author and publisher.

for many hundreds of continuous bases) at equivalent sites along their DNA chains, which can result in crossover or DNA-repair events almost randomly at any site along the pair of parental DNA molecules. This can thereby result in a change in linkage, or proximity on the same chromosome, for various small (but nevertheless significant) chromosomal differences situated along the lengths of the two recombining DNA molecules. If the two recombining DNA chains are generally homologous, but contain scattered differences from one to the other (e.g. a few percent difference or more for the *E. coli* versus *Salmonella* chromosomes) recombination can still occur, but is more infrequent with increasing differences in sequences. This nearly homologous configuration is known as homeologous recombination.

Homologous recombination can thus occur following gene transfer between closely related organisms (see later discussion). However, homologous recombination also occurs, very frequently, even between elements within one cell. For instance, crossovers between some of the seven homologous copies of rRNA operons can occur during vegetative growth to produce large genetic duplications or inversions. These rearrangements are unstable and readily recombine back to the normal haploid state. Nevertheless their mere existence (in up to one-third of a growing population of cells) makes possible various changes in gene dosage or gene arrangement, which likely contributes to the evolutionary flux over long periods of time due to rare accompanying recombination events that are sometimes nonhomologous (or illegitimate).

2. Site-specific recombination

As the name implies, this form of recombination is a crossover event between two DNA double helices, which is catalyzed to occur at unique sites on the DNA strands, defined by the local DNA sequence involving usually 20–30 bases. A specialized enzyme recognizes these sequences, on both parental molecules, and causes a double-strand breakage and rejoining event that exchanges the partners of flanking DNA. The crossover is completely conservative, that is, no bases are added or lost at the crossover site. One configuration of site-specific recombination enables the circular form of a lysogenic phage, such as lambda (found in *E. coli* K-12) or P22 (one of a large family of related bacteriophages found in most natural *Salmonella* isolates), to integrate into the chromosome (and thus become a stable lysogen), or to be excised from it (and thus begin to replicate vegetatively). See Fig. 35.2 (site-specific, upper).

Another DNA configuration involved in site-specific recombination involves a hairpin-like intermediate such that the end result of the crossover is an inversion of the stretch of DNA located between the two crossover sites (Fig. 35.2, site-specific, lower). An example of this occurs in *Salmonella* and results in a change in gene expression for two different genes for the production of flagellin, which is assembled into filaments on the surface of the cell (see Fig. 35.3). By switching the gene expression in this way, *Salmonella* is able to change its filament antigenic structure (i.e. undergo phase variation) and thus reduce attack by host immune systems. Another mechanism for phase variation also exists in some strains, in which methylation of certain critical adenine residues will activate or deactivate gene expression, and this methylation pattern can be quasi-stably inherited for many generations, until it flip-flops back to a nonmethylated state, which reverses the antigenic phase.

3. Transpositional recombination

As in the case of site-specific recombination, certain specialized short DNA sequences are involved in recombination involving DNA elements called transposons. Transposons are sequences of DNA, usually in the size range of 700–10,000 bases, which can move by recombination from one location in the genome to any of a multitude of other sites (targets). The specialized sequences that promote this recombination are usually 15–30 bases long and located at the two ends of the transposon as an inverted repeat. The DNA between the two ends can encode a number of genes whose functions are either required for the transpositional recombination (e.g. transposase, resolvase) or other functions that alter cell phenotype, such as antibiotic resistance. Transposons that do not encode any internal genes except those needed for transposition are called insertion sequences (IS). The *E. coli* chromosome contains several copies of five IS, and approximately 15% of the spontaneous mutations in *E. coli* occur due to the movement of these IS to new sites. None of these particular IS are normally found in *Salmonella*, but a different IS specific to *Salmonella* strains is normally present somewhere on its chromosome.

Transposition events can either involve the movement of the entire original transposon DNA sequence to a new site (conservative transposition) or a replicative process in which the transposon is replicated to form two copies, one of which is inserted at the new (target) site and the other of which is retained at the original site (replicative transposition) (see Fig. 35.2). Even in the case of conservative transposition, a small amount of DNA synthesis is involved, in which a few of

FIGURE 35.3 Mechanism for flagellar phase variation in *S. typhimurium* (i.e., the alternate expression of two structural genes for flagellin, an H antigen). The two genes, *fliC* (formerly named H1) and *fljB* (formerly named H2), are distant from each other on the chromosome at 43 and 61 min, respectively (see Fig. 35.1). The promoter for the *fljB* operon is part of a region of the chromosome that is bounded by an inverted repeat (white or shaded arrow bars), which can be inverted by site-specific recombination mediated by the Hin invertase protein, a product of gene *hin* in the invertable region. In the orientation shown at the top of the figure (phase 2), the promoter for the *fljB* operon (P_{fljB}) is correct and FljB or phase 2 flagellin is synthesized, together with the repressor of the phase 1 *fliC* operon, the *fljA* gene product (formerly named rh1). In the other orientation (phase 1), shown at the bottom of the figure, P_{fljB} is separated from the operon it promotes and neither the phase 2 flagellin nor the phase 1 repressor is synthesized. The *fliC* operon is therefore expressed, and FliC or phase 1 flagellin is synthesized. Adapted from Macnab, R. In Neidhardt, F., et al. (1996), p. 137, with permission from the author and the American Society for Microbiology.

bases at the target site are copied to create a small duplication at each end of the newly inserted transposon.

IV. GENE TRANSFER BETWEEN CELLS

A. Conjugation

In Section II, it was noted that most *Salmonella* strains and many *E. coli* strains carry fertility factors (conjugative plasmids) that can promote gene transfer from cell to cell by conjugation. Furthermore, the F-like plasmids in *E. coli* and the pSLT-like plasmids in *Salmonella* have a number of genes in common, and considerable homology between them. These facts strongly imply that over evolutionary history there has been considerable cross-talk and gene transfer among these strains. The particular F factor in *E. coli* strain K-12 is (fortunately for J. Lederberg and other early investigators in the discovery and study of conjugation) highly efficient for promoting conjugation

between F^+ cells (those that carry the F factor as a plasmid) and F^- cells (those which have no F factor in any form). This is due to a mutation on the K-12 F factor in the regulatory system that, for the vast majority of fertility factors, represses the genes for conjugation. With these “normal” conjugative plasmids, this repression keeps all the cells except about 1/1000 from acting as donors. At any given time any one of the cells can, with a probability of 1/1000, become temporarily derepressed for conjugative functions and cause its own transfer into an F^- cell (thus converting it into an F^+ cell). Immediately following this transfer into the F^- cell, there is a delay before the repression of the conjugative functions builds up. Thus, such a newly formed F^+ cell is temporarily able to conjugate (act as a donor) efficiently again, with another F^- cell. In this way a rapid epidemic spread of conjugative plasmids can move into a new population of F^- cells when the opportunity arises.

On rare occasions, an F-like plasmid can recombine with the chromosome to form an Hfr (high frequency of recombination) cell (see Fig. 35.4). In the process of

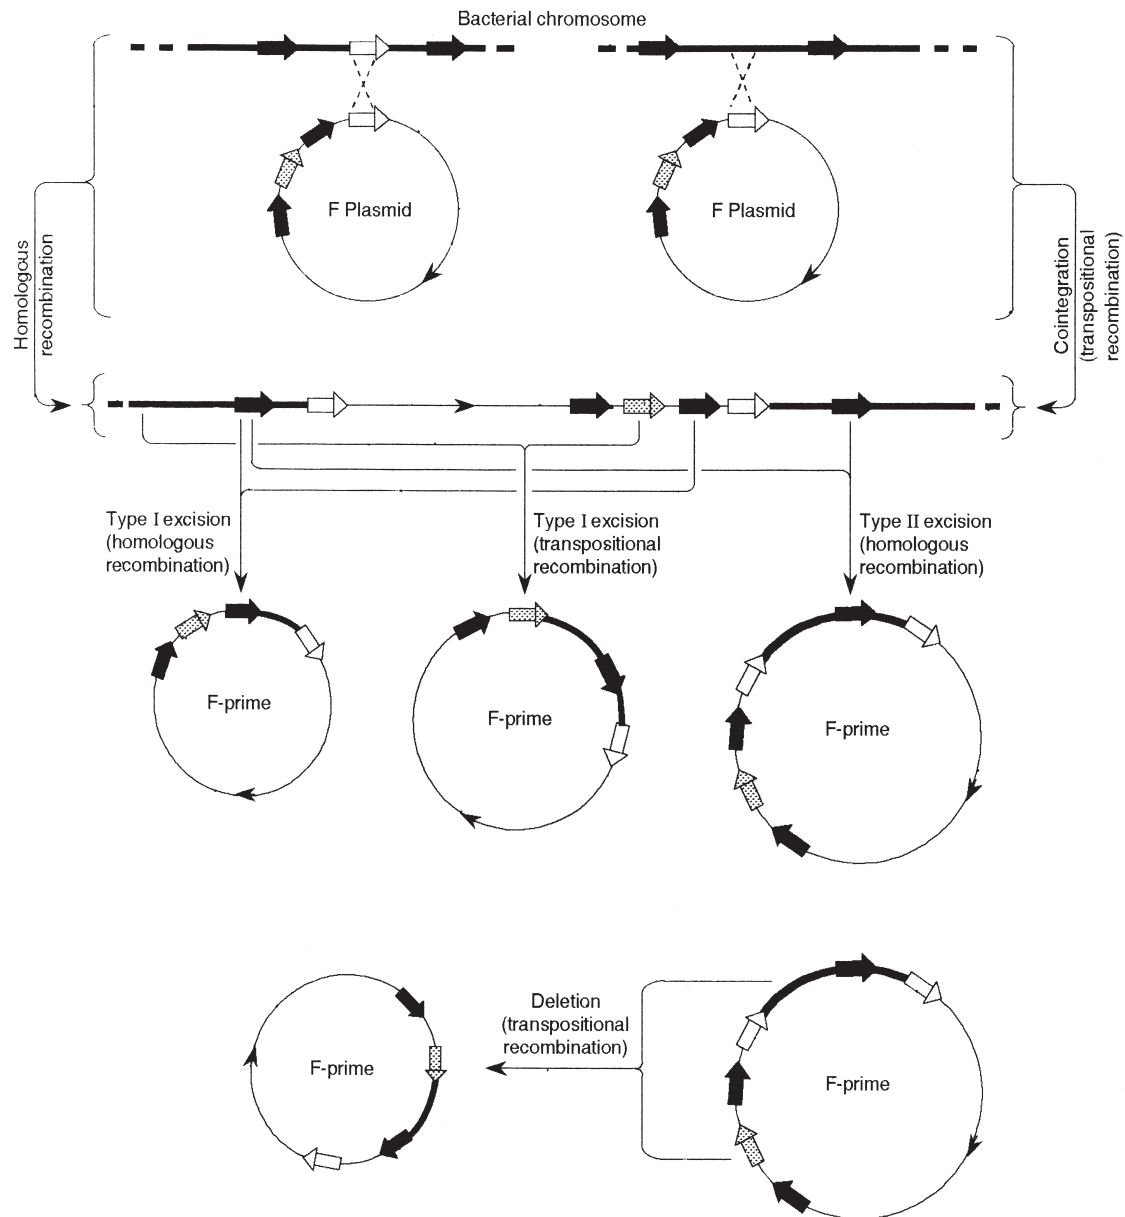

FIGURE 35.4 Interconversion between various states of the F factor in *E. coli*. The top heavy horizontal lines represent parts of the chromosome, with arrows that represent the various positions of IS. IS that are also located on the F factor (thin circular line) can recombine with the chromosome either by homologous recombination with a chromosomal IS of the same type (top left), or by transpositional recombination at a chromosomal site where there is not normally an IS (top right). The resulting chromosome with the integrated F factor (center horizontal line) is called Hfr. The Hfr chromosome can undergo subsequent recombination events, and they produce plasmids (F-primes) that carry most or all of the F factor plus a section of the chromosome. From Holloway, B. and Low, B. *In* Neidhardt, F., *et al.* (1996), p. 2414, with permission from the author and the American Society for Microbiology.

conjugation from such a cell, the transfer of the normal leading region (next to a specific site called the origin of transfer, indicated by the small arrowhead in Fig. 35.4), leads to the transfer of chromosomal genes because in the Hfr state the F factor and chromosome form one continuous DNA molecule. Considerable amounts of chromosomal genetic information can be transferred in this way, although the transfer process

tends to be interrupted spontaneously so that the genes furthest around the chromosome have the least chance of being transferred.

B. Transduction

Recall that a large family of lysogenic bacteriophages related to P22 exist among wild-type *Salmonella*

strains. It so happens that when phage P22 is replicating lytically in a cell and being packaged into new phage particles, occasionally (about once in every 30 times) the packaging process makes a mistake and packages a segment (about 1%) of the bacterial genome instead of the newly replicated P22 DNA. These aberrant particles are called transducing particles and can come out of the cell along with the burst of normal new phage particles. The transducing particles can travel to another cell and inject in the genomic DNA, followed in some cases by recombination into the new cell's genome. The analogous processes occur in *E. coli* strains with a phage known as P1, which can package about 2% of the genome into transducing particles. The process, discovered in 1952 by Zinder and Lederberg, is called generalized transduction and it most likely has had a major role in the horizontal transfer of genetic information among enteric bacteria. In some cases, the transduced chromosomal DNA fragment does not recombine into the chromosome but forms a stable (nonreplicating) structure that continues to be unilaterally inherited by only one of the daughter cells at each division. If the transducing fragment carries a functional gene that allows the transduced cell to grow on selective medium, only a tiny colony will grow because only one of the two daughter cells after each division will divide again. This is termed abortive transduction and has been useful in determining functional complementation between mutated genes.

Another mode of transduction, termed specialized transduction, is distinctly different from generalized transduction. Specialized transduction involves the excision of a chromosomally located lysogenic bacteriophage (i.e. in the prophage state) to form a circular replicating form. However, rarely, this excision event is imprecise and sometimes involves a crossover within the adjacent bacterial chromosomal DNA (analogous to F-prime formation, Fig. 35.4), such that the replicating phage and subsequent phage particles produced contain a small amount (a few genes) of chromosomal DNA. This DNA can thus be carried by the progeny phage particles and injected into new host cells, followed by possible recombination events. Thus, in specialized transduction only genes close to the prophage integration site can be transduced. Moreover, the altered phage particles carrying the chromosomal fragment can be grown and amplified to produce large quantities of the specific chromosomal genes for experimental purposes.

C. Transformation

The uptake of naked DNA by bacteria and the subsequent inheritance of its genetic information in the

genome occur naturally in some gram-positive and gram-negative bacterial species such as *Streptococcus pneumoniae*, *Bacillus subtilis*, *Haemophilis*, and *Acinetobacter*, but only under certain growth conditions that induce competence, or the ability to take up DNA. In contrast, *E. coli* and *Salmonella* are not known to have this natural competence for DNA uptake, and it is unlikely that transformation has contributed significantly to their evolutionary genomic development. However, laboratory methods have been devised that promote the uptake of DNA into *E. coli* and *Salmonella*, thus greatly facilitating their use in molecular biological studies. These methods for artificially induced transformation competence generally involve either treatment with di- or multivalent cations (e.g., Ca^{2+} , Mg^{2+}) and heat shock, which is believed to partially disrupt the lipopolysaccharide in the outer membrane (chemical competence), or treatment with a brief pulse of high-voltage electricity (electroshock), which renders the membrane temporarily permeable to a variety of macromolecules including DNA.

Exotoxins

Joseph T. Barbieri

Medical College of Wisconsin

GLOSSARY

AB structure–function The structure–function organization of most bacterial exotoxins; the **A** domain comprises catalytic activity and the **B** domain comprises the binding and translocation domains.

exotoxin A soluble protein produced by a microorganism that can enter a host cell and catalyze the covalent modification of a cellular component to alter host-cell physiology.

heat-stable enterotoxins Soluble peptides that are secreted by bacteria, which bind to host cells and stimulate a signal transduction pathway within the host cell.

mechanism of action The specific reaction by which each exotoxin catalyzes to covalently modify a host-cell component, such as the ADP-ribosylation of elongation factor-2 by diphtheria toxin.

pore-forming toxins Soluble proteins that are secreted by bacteria, which bind to the surface of the host cell and oligomerize to form a pore to release soluble components from the host cell.

posttranslational modification A covalent modification to a cellular component that occurs subsequent to its synthesis.

proenzyme The form in which exotoxins are secreted by bacteria; these are processed to exhibit catalytic activity.

super antigens Soluble proteins that are secreted by bacteria and bind to the major histocompatibility

complex of T lymphocytes. This stimulates antigen-independent proliferation of T lymphocytes.

toxoid The detoxified form of an exotoxin that is used for immunization. Conventional toxoiding is achieved with chemicals such as formalin; genetic engineering approaches have also been used to produce toxoids.

type III secreted cytotoxins Soluble proteins that are translocated into the host-cell cytoplasm via a type III secretion apparatus by host-cell surface-bound bacteria.

vaccination The administration of an immunogen (toxoid) to stimulate an immune response that protects the host from infection by the microorganism that produces the immunogen.

Exotoxins are a group of soluble proteins that are secreted by the bacterium, enter host cells, and catalyze the covalent modification of a host-cell component(s) to alter the host-cell physiology. Both gram-negative and gram-positive bacteria produce exotoxins. A specific bacterial pathogen may produce a single exotoxin or multiple exotoxins. Each exotoxin possesses a unique mechanism of action, which is responsible for the elicitation of a unique pathology. Thus, the role of exotoxins in bacterial pathogenesis is unique to each exotoxin. *Corynebacterium diphtheriae* produces diphtheria toxin, which is responsible for the systemic pathology associated with diphtheria, whereas *Vibrio cholerae* produces cholera toxin, which is responsible for the diarrheal pathology associated with cholera. Exotoxins

vary in their cytotoxic potency, with the clostridial neurotoxins being the most potent exotoxins of humans. Exotoxins also vary with respect to the host that can be intoxicated. Exotoxin A of *Pseudomonas aeruginosa* can intoxicate cells from numerous species, whereas other toxins, such as diphtheria toxin are more restricted in the species that can be intoxicated. Some bacterial toxins, such as pertussis toxin, can intoxicate numerous cell types, whereas other toxins, such as the Clostridial neurotoxins, show a specific tropism and intoxicate only cells of neuronal origin. Bacterial exotoxins catalyze specific chemical modifications of host cell components, such as the ADP-ribosylation reaction catalyzed by diphtheria toxins or the deamidation reaction catalyzed by the cytotoxic necrotizing factor produced by *Escherichia coli*. These chemical modifications may either inhibit or stimulate the normal action of the target molecule to yield a clinical pathology. Bacterial exotoxins possess an **AB** structure–function organization, in which the **A** domain represents the catalytic domain and the **B** domain comprises the receptor-binding domain and the translocation domain. The translocation domain is responsible for the delivery of the catalytic **A** domain into an intracellular compartment of the host cell.

Many bacterial exotoxins can be chemically modified to toxoids that no longer express cytotoxicity, but may retain immunogenicity. Studies have shown that bacterial toxins can also be genetically engineered to toxoids, which may lead to a wider range of vaccine products. Exotoxins have also been used as therapeutic agents to correct various disorders, including the treatment of muscle spasms by botulinum toxin. Nontoxic forms of exotoxins have been used as carriers for the delivery of heterologous molecules to elicit an immune response and as agents in the development of cell-specific chemotherapy. In addition, bacterial toxins have been used as research tools to assist in defining various eukaryotic metabolic pathways, such as G-protein-mediated signal transduction.

I. CLASSIFICATION OF EXOTOXINS

Exotoxins are soluble proteins produced by microorganisms that can enter a host cell and catalyze the covalent modification of a cellular component(s) to alter the host-cell physiology. The term “host cell” refers to either vertebrate cells or cells of lower eukaryotes, such as protozoa because some bacterial exotoxins intoxicate a broad range of host cells. The recognition that some pathogenic bacteria produced soluble components that were capable of producing

the pathology associated with a particular disease was determined in the late nineteenth century. Roux and Yersin observed that culture filtrates of *Corynebacterium diphtheriae* were lethal in animal models and that the pathology elicited by the culture filtrate was similar to that observed during the infection by the bacterium. Subsequent studies isolated a protein, diphtheria toxin, from the toxic culture filtrates and observed that the administration of purified diphtheria toxin into animals was sufficient to elicit the pathology ascribed to diphtheria. Diphtheria toxin is a prototype exotoxin and has been used to identify many of the biochemical and molecular properties of bacterial exotoxins.

The ability of a bacterial pathogen to cause disease frequently requires the production of exotoxins, but the mere ability to produce a toxin is not sufficient to cause disease. Cholera toxin is the principal virulence factor of *Vibrio cholerae*. Administration of micrograms of purified cholera toxin to human volunteers elicits a diarrheal disease that mimics the magnitude of the natural infection. Nonetheless, nonvirulent toxin-producing strains of *V. cholerae* have been isolated and shown to lack specific biological properties, such as motility or chemotaxis. Similarly, although anthrax toxin is the principal toxic component of *Bacillus anthracis*, nonvirulent toxin-producing strains of *B. anthracis* have been isolated and shown to lack the ability to produce a polyglutamic acid capsule. An exception to this generalization is the intoxication elicited by the botulinum neurotoxins, in which ingestion of the preformed toxin is responsible for the elicitation of disease; food poisoning by botulinum neurotoxins is an intoxication, rather than an infection by a toxin-producing strain of *Clostridium botulinum*.

Bacterial exotoxins are classified according to their mechanisms of action. The covalent modifications of host-cell components, which are catalyzed by bacterial exotoxins, include ADP-ribosylation, deamidation, depurination, endoproteolysis, and glucosylation (Table 36.1). Most cellular targets of bacterial exotoxins are proteins, although there are exceptions such as shiga toxin, which catalyzes the deadenylation of ribosomal RNA. In addition to exotoxins, there are several other classes of toxins that are produced by bacterial pathogens, including the pore-forming toxins, type III-secreted cytotoxins, heat-stable enterotoxins, and superantigens. Each of these toxins fails to perform one of the properties associated with exotoxins. The pore-forming toxins are not catalytic in their action, but instead disrupt cell physiology through the formation of pores in the host-cell plasma membrane. The type III-secreted cytotoxins can not enter host cells as soluble proteins, but instead are translocated

TABLE 36.1 Properties of bacterial exotoxins

Modification	Exotoxin	Bacterium	AB	Target	Contribution to pathogenesis
ADP-ribosylation	Diphtheria toxin	<i>C. diphtheriae</i>	AB	Elongation factor-2	Inhibition of protein synthesis
	Exotoxin A	<i>P. aeruginosa</i>	AB	Elongation factor-2	Inhibition of protein synthesis
	Cholera toxin	<i>V. cholerae</i>	AB5	Gs α	Inhibition of GTPase activity
	Heat-labile enterotoxin	<i>E. coli</i>	AB5	Gs α	Inhibition of GTPase activity
	Pertussis toxin	<i>B. pertussis</i>	AB5	Gi α	Uncoupled signal transduction
	C2	<i>C. botulinum</i>	A-B	actin	Actin depolymerization
Glucosylation	Lethal toxin	<i>C. sordelli</i>	AB	Ras	Inhibition of effector interactions
	Toxin A and B	<i>C. difficile</i>	AB	RhoA	Inhibition of Rho signaling
Endoprotease	Anthrax toxin	<i>B. anthracis</i>	A-B	Aedema factor A, lethal factor	Adenylate cyclase Endoprotease?
	Botulinum toxin (A-F)	<i>C. botulinum</i>	AB	Vesicle proteins	Inhibition of vesicle fusion
	Tetanus toxin	<i>C. tetani</i>	AB	Vesicle protein	Inhibition of vesicle fusion
Deamidation	Cytotoxic necrotizing factor	<i>E. coli</i>	AB	RhoA	Stimulation of RhoA
Deadenylation	Shiga toxin	<i>Shigella</i> spp.	AB5	28S RNA	Inhibition of protein synthesis
	Verotoxin	<i>E. coli</i>	AB5	28S RNA	Inhibition of protein synthesis

directly into the host cell by the type III secretion apparatus of the cell-bound bacterium. The heat-stable enterotoxin and superantigens do not enter the intracellular compartment of the host cell, and elicit host-cell responses by triggering signal-transduction pathways upon binding to the host-cell membrane. In this article, initial emphasis will be placed on the molecular properties of bacterial exotoxins, with a subsequent description of the general properties of pore-forming toxins, type III-secreted cytotoxins, heat-stable enterotoxins, and superantigens.

The pathology elicited by a specific exotoxin results from the catalytic covalent modification of a specific host-cell component. Although diphtheria toxin and cholera toxin are both bacterial ADP-ribosylating exotoxins, the pathogenesis elicited by each exotoxin is unique. This is due to the fact that diphtheria toxin ADP-ribosylates elongation factor-2, resulting in the inhibition of protein synthesis and subsequent cell death, whereas cholera toxin ADP-ribosylates the Gs α component of the heterotrimeric protein, which stimulates the activity of adenylate cyclase. The stimulation of adenylate cyclase elevates intracellular cAMP and the subsequent secretion of electrolytes and H₂O from the cell, resulting in the clinical manifestations of cholera.

II. GENERAL PROPERTIES OF EXOTOXINS

A. Genetic organization of exotoxins

The genes encoding bacterial exotoxins may be located on the chromosome or located on an extrachromosomal

element, such as a plasmid or a bacteriophage. Elegant experiments characterizing diphtheria toxin showed that the gene encoding this exotoxin was located within the genome of the lysogenic β -phage. Although both nonlysogenic and lysogenic strains of *C. diphtheriae* could establish local upper-respiratory-tract infection, only strains of *C. diphtheriae* lysogenized with a β -phage that encoded diphtheria toxin were capable of eliciting systemic disease. This established a basic property for the pathology elicited by bacteria that produce exotoxins; bacteria establish a localized infection and subsequently produce an exotoxin, which is responsible for pathology distal to the site of infection.

Most exotoxins are produced only during specific stages of growth with the molecular basis for the regulation of toxin expression varying with each bacterium. This differential expression often reflects a complex regulation of transcription, including responses to environmental conditions, such as iron. Multisubunit toxins are often organized in operons to allow the coordinate expression of their subunit components.

B. Secretion of exotoxins from the bacterium

Most bacteria secrete exotoxins across the cell membrane by the type II secretion pathway. The secretion of exotoxins by the type II secretion pathway was predicted by the determination that the amino terminus of mature exotoxins had undergone proteolysis relative to the predicted amino acid sequence. Type II secretion is also called the general secretion pathway. Type II secretion involves the coordinate translation and secretion of a nascent polypeptide across the cell

membrane. During the translation of the mRNA that encodes a type II-secreted protein, the nascent polypeptide contains an amino-terminal leader sequence that is targeted to and secreted across the cell membrane. After secretion across the cell membrane, the nascent polypeptide folds into its native conformation and the leader sequence is cleaved by a periplasmic leader peptidase to yield a mature exotoxin.

Some gram-negative bacteria export the assembled exotoxin from the periplasm into the external environment via a complex export apparatus. While the heat-labile enterotoxin of *Escherichia coli* remains localized within the periplasmic space, *V. cholerae* and *Bordetella pertussis* assemble their respective exotoxins, cholera toxin and pertussis toxin, within the periplasm and then transport the mature exotoxin into the external environment. Although the multiple protein components of the export apparatus have been identified, the mechanism for export across the outer membrane remains to be resolved.

C. Bacteria produce and secrete exotoxins as proenzymes

Although one property of a bacterial exotoxin is the ability to intoxicate sensitive cells, early biochemical studies observed that *in vitro* many bacterial exotoxins possessed little intrinsic catalytic activity. These perplexing observations were resolved with the determination that bacteria produce and secrete exotoxins as proenzymes, which must be activated (processed) to express catalytic activity *in vitro*. Because exotoxins intoxicate sensitive cells, the requirements for *in vitro* activation reflect the activation steps *in vivo*. Each exotoxin requires specific conditions for activation, including proteolysis, disulfide-bond reduction, or association with a nucleotide or a eukaryotic accessory protein. Some activation processes result in the release of the catalytic A domain from the B domain, whereas other activation processes appear to result in a conformational change in the catalytic A domain, rendering it catalytically active. Some exotoxins require sequential activation steps. Diphtheria toxin is activated by limited proteolysis, followed by disulfide-bond reduction (see Fig. 36.1).

The determination of the activation mechanism of exotoxins has also provided insight into several physiological pathways of host cells. The eukaryotic protein, ARF (ADP-ribosylation factor), which activates cholera toxin *in vitro*, was subsequently shown to play a central role in vesicle fusion within the eukaryotic cell. The ability of a host-cell extract to activate cholera toxin is often used as a sign of the presence of ARF. Similarly, the characterization of the mechanisms that

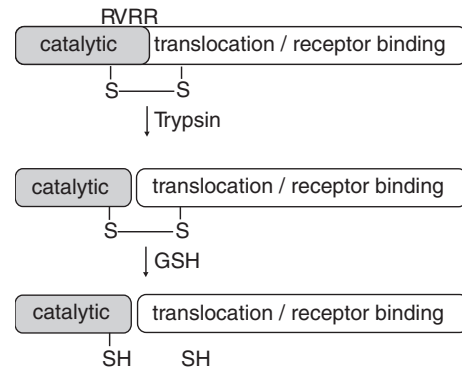

FIGURE 36.1 Bacterial exotoxins are produced as proenzymes. Most bacterial exotoxins are produced as proenzymes that undergo processing to express catalytic activity. The sequential processing of diphtheria toxin involves protein cleavage at a trypsin-sensitive site in the carboxyl terminus of the A domain (Arg-Val-Arg-Arg, RVRR). The A and B domains are connected by a disulfide bond, which is reduced by agents such as reduced glutathione (GSH).

pertussis toxin and cholera toxin use to intoxicate eukaryotic cells has provided insight into the pathways for eukaryotic G protein-mediated signal transduction. The ability of pertussis toxin to inhibit the action of a ligand in the stimulation of a signal-transduction pathway is often used to implicate a role for G proteins in that signaling pathway.

D. AB Structure–function properties of exotoxins

Most bacterial exotoxins possess AB structure–function properties. (see Fig. 36.2). The A domain is the catalytic domain, whereas the B domain includes the translocation and binding domains of the exotoxin. Exotoxins are organized into one of several general types of AB organization. The simplest AB organization is represented by the diphtheria toxin, in which the A domain and B domain are contained in a single protein. Diphtheria toxin is the prototype for this class of AB exotoxin. Diphtheria toxin is a 535-amino-acid protein in which the amino terminus constitutes the ADP-ribosyltransferase domain and the carboxyl terminus comprises the translocation domain and receptor-binding domain. The AB₅ exotoxins are composed of six proteins that are noncovalently associated as an oligomer. Cholera toxin is the prototype for the AB₅ exotoxin. The A domain of cholera toxin constitutes the ADP-ribosyltransferase domain, whereas the B₅ domain is composed of five identical proteins, forming a pentamer. This is organized into a ring structure, on which the A domain is positioned. The five proteins that make up the B domain may be identical, as is the case for cholera toxin and the heat-labile enterotoxin of

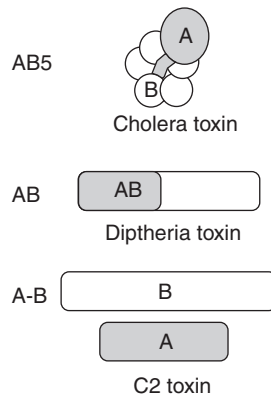

FIGURE 36.2 Bacterial exotoxins possess **AB** structure–function organization. There are three general **AB** organizations of bacterial exotoxins. The **A** domain (shaded) represents the catalytic domain whereas the **B** domain comprises the translocation and receptor-binding domains. **AB5** is represented by cholera toxin of *V. cholerae*, which is composed of six noncovalently associated proteins. **AB** is represented by diphtheria toxin of *C. diphtheriae*, in which the **A** and **B** domain are included in a single protein. **A-B** is represented by C2 toxin of *Clostridium botulinum*, which is composed of two nonassociated proteins; the two proteins associate after the binding and processing of the **B** component on the host-cell membrane.

E. coli, or may be different proteins that form a non-symmetrical ring structure, as observed with the **B** oligomer of pertussis toxin.

The third class of **AB** exotoxin is composed of proteins that are not associated in solution, but that do associate following the binding and processing of the **B** domain to the host cell. C2 toxin is an example of this class of **A-B** exotoxin. C2 toxin is a bipartite exotoxin composed of a protein that encodes the catalytic **A** domain and a separate protein that encodes the **B** domain. The **A** domain protein of C2 toxin ADP-ribosylates actin. The **B** domain protein of C2 binds to sensitive cells and is nicked by a eukaryotic protease. The processed **B** components oligomerize and are then capable of binding either of the **A** domain proteins.

A new class of toxin organization has recently been recognized in which the **A** domain is a protein and the bacterium is directly responsible for its delivery into the cell. The bacterium binds to the eukaryotic cell and uses a type III secretion apparatus to deliver cytotoxins, also called effector proteins, into the intracellular compartment of the cell. The YopE cytotoxin of *Yersinia* is the prototype of this group of toxins. These cytotoxins do not conform to the strict definition of exotoxins because the purified cytotoxins cannot directly enter to modify host-cell physiology and are not included with the family of bacterial exotoxins. They are termed “type III secreted cytotoxins”, and are described later.

Although the **A** domain possesses the catalytic activity of the exotoxin, the **B** domain possesses two

specific functions, receptor binding and translocation capacity. Each exotoxin uses a unique host-cell surface component as a receptor. The cell surface receptor for each exotoxin may be specific. The cell surface receptor for cholera toxin is the ganglioside, GM1, whereas diphtheria toxin binds directly to the epidermal growth factor precursor. In contrast, the binding of pertussis toxin appears to be less specific, as pertussis toxin is able to bind numerous cell surface proteins. The ability to bind its cell surface receptor is an absolute requirement for an exotoxin to intoxicate a host cell because the deletion of the receptor-binding domain renders the exotoxin essentially noncytotoxic. After binding to the cell surface, some exotoxins are proteolytically processed or are processed during endocytic vesicle transport.

The second function of the **B** domain includes translocation capacity, which is responsible for the delivery of the **A** domain across the cell membrane. The presence of a translocation domain was predicted from early structure–function studies of diphtheria toxin, which showed that in addition to the catalytic domain and receptor-binding domain, a third function was required for the efficient expression of cytotoxicity. This third function was subsequently shown to correspond to a region of diphtheria toxin that had the propensity to interact with membranes. The crystal structure of diphtheria toxin revealed the presence of three distinct domains, representing the catalytic, translocation, and receptor-binding functions.

E. Exotoxins enter host cells via distinct pathways

Although **A** domain translocation is one of the least understood aspects of the intoxication process of exotoxins, there are several general themes that are involved in translocation of the **A** domain across the cell membrane. One translocation mechanism uses a pH gradient within the endosome to stimulate protein conformational changes in the **B** domain, making it competent to interact with the endocytic vesicle. After insertion into the endocytic membrane, the **B** domain generates a pore that is believed to be involved in the translocation of the **A** domain across the vesicle membrane in an unfolded form. After the translocation across the endocytic membrane, the **A** domain refolds to its native conformation. Subsequent to translocation of the **A** domain across the vesicle membrane, reduced glutathione may reduce the disulfide that connects the **A** domain with the **B** domain, and release the **A** domain into the cytoplasm. The potency and catalytic potential of exotoxins was demonstrated by the observation that the introduction of one molecule of the catalytic domain of diphtheria toxin into the intracellular cytoplasm was

sufficient to inhibit host-cell physiology, resulting in cell death.

Other toxins, such as cholera toxin and exotoxin A of *Pseudomonas aeruginosa*, appear to use retrograde transport to enter the interior regions of the cell. Movement appears to occur through retrograde transport from the endosome to the Golgi apparatus and ultimately to the endoplasmic reticulum. Many exotoxins that are ultimately delivered to the endoplasmic reticulum possess a KDEL (Lys-Asp-Glu-Leu)-like retention signal sequence on their carboxyl terminus. Although the details for the actual transport pathway remain to be determined, studies with chimeric proteins have shown that the introduction of a KDEL retention sequence is sufficient to retrograde transport a protein, which is normally delivered only to the early endosome, into the endoplasmic reticulum. Thus, there is physiological precedence for the use of the KDEL sequence to retrograde transport exotoxins toward the endoplasmic reticulum. One of the basic questions concerning the intoxication process of these exotoxins is the actual mechanism of translocation and whether or not eukaryotic proteins assist in the translocation process.

F. Covalent modification of host-cell components by exotoxins

Exotoxins use several unique mechanisms to covalently modify host-cell components. The major classes of reactions are the covalent addition of a chemical group to the target protein, the cleavage of a chemical group from a target protein, or the endoproteolytic cleavage of a peptide bond of the target protein.

The ADP-ribosylation of host proteins is the prototype mechanism of action of bacterial exotoxins. Numerous bacterial exotoxins catalyze the ADP-ribosylation of specific host proteins and elicit physiological changes. In the ADP-ribosylation reaction, exotoxins use the oxidized form of nicotinamide adenine dinucleotide (NAD) as the substrate, and transfer the ADP-ribose portion of NAD to a specific amino acid via an *N*-glycosidic linkage of ADP-ribose onto the host target protein. The specific type of amino acid that is ADP-ribosylated within the target protein varies with the specific exotoxin. ADP-ribosylation may either inactivate or stimulate the activity of the target protein. Diphtheria toxin ADP-ribosylates elongation factor-2 on a post-translationally modified histidine residue called diphthamide. ADP-ribosylated elongation factor-2 is unable to perform its translocation of nascent polypeptides in the ribosome, which results in the inhibition of protein synthesis and subsequent cell death. In contrast, cholera toxin ADP-ribosylates the G α component of a heterotrimeric G protein.

ADP-ribosylated G α is locked in an active conformation, which results in the stimulation of adenylate cyclase and the subsequent elevation of intracellular cAMP. Likewise, deamidation of Gln63 of RhoA by *E. coli* cytotoxic necrotizing factor (CNF) results in a constitutively active RhoA protein. Note that although most host targets for exotoxins are proteins, Shiga toxin catalyzes the deadenylation of a specific adenine on 28S RNA.

Recall that each exotoxin modifies a specific host-cell component, which is responsible for the specific pathology elicited by that exotoxin. Although there are no absolute rules for the types of proteins targeted for covalent modification, the most frequent targets are nucleotide-binding proteins that are involved in signal-transduction pathways, including both the heterotrimeric G-proteins and the small-molecular-weight GTP-binding proteins of the Ras superfamily. It is not clear whether this class of host protein is targeted for modification due to the presence of a common structural motif, or to its critical role in host-cell metabolism.

G. Molecular and structural properties of bacterial exotoxins

Early biochemical studies provided significant advances in defining the structure–function properties of exotoxins, resolving many of the exotoxin mechanisms of action and developing the concept that exotoxins have **AB** organization. Molecular genetics and structural biology have extended the earlier studies and provided a more detailed understanding of the biochemical and molecular relationships among the exotoxins. The biochemical characterization of diphtheria toxin and exotoxin A (ETA) of *Pseudomonas aeruginosa* showed that these two exotoxins catalyzed kinetically identical reactions during the ADP-ribosylation of elongation factor-2. In addition, both diphtheria toxin and ETA were shown to possess an active site glutamic acid, which was subsequently shown to be a signature property of exotoxins that catalyze the ADP-ribosyltransferase reaction. These observations predicted that ADP-ribosylating exotoxins would possess considerable primary amino acid homology. Thus, the determination that the genes encoding diphtheria toxin and ETA shared little primary amino acid homology was unexpected. This paradox was resolved after the analysis of the three-dimensional structures of ETA and the heat-labile enterotoxin (LT) of *E. coli*, and subsequently confirmed with diphtheria toxin. The three-dimensional structures of ETA and LT showed little similarity in their respective receptor-binding domains and translocation domains; however, the catalytic domains of ETA and LT, which are composed of seven

discontinuous regions of each protein, could be superimposed on each other despite possessing homology at only three of the 43 amino acids. One of the homologous amino acids in ETA and LT was the signature active site glutamic acid. This was a remarkable finding because ETA and LT ADP-ribosylate different host target proteins and possess different **AB** organization. A common theme has evolved for describing the structure–function properties of this family of bacterial exotoxins in which the ADP-ribosylating exotoxins possess a conserved three-dimensional structure in their active sites, despite the lack of primary amino acid homology. These findings have provided a framework for the study of other classes of exotoxins produced by divergent groups of bacteria.

III. CONVERSION OF EXOTOXINS INTO TOXOIDS

A. Chemical detoxification of bacterial exotoxins

Shortly after the determination that toxic components were associated with bacterial pathogens, several studies showed that cell extracts or cell cultures of a pathogen could be treated with chemical denaturants, such as formalin, to produce nontoxic immunogenic material that could prevent the disease associated with that pathogen. In the case of diphtheria toxin and tetanus toxin, chemical modification with formalin produced toxoids that were used as acellular vaccines in large-scale immunizations. This resulted in a remarkable decrease in the incidence of both diphtheria and tetanus within the populations that were immunized. In areas where these toxoids are not administered, diphtheria and tetanus remain clinically important diseases. In addition to formalin, other chemicals have been used to detoxify bacterial exotoxins, including glutaraldehyde and hydrogen peroxide. In contrast, the chemical toxoiding of other exotoxins, such as cholera toxin and pertussis toxin, has been more difficult because the treatment of these toxins with denaturants often results in a reduction of immunogenicity. Thus, there is a need to develop alternative strategies for eliminating the cytotoxicity of certain exotoxins without compromising their immunogenicity.

B. Genetic detoxification of bacterial exotoxins

Developments in genetic engineering have provided an opportunity to produce recombinant forms of bacterial exotoxins that possess greatly reduced toxicity, but retain immunogenicity. The use of genetic

engineering to develop a toxoid of pertussis toxin has been successful. The whole-cell pertussis vaccine is composed of a chemically treated preparation of *Bordetella pertussis*, which is effective in the elicitation of a protective immune response after mass immunization. However, the whole-cell pertussis vaccine is acutely reactive when administered to children. Pertussis toxin, a primary virulence determinant of *B. pertussis*, is an exotoxin that ADP-ribosylates the $G_{i\alpha}$ component of heterotrimeric G proteins and effectively uncouples signal transduction between the G protein-coupled receptor and the G protein. Genetically engineered forms of pertussis toxin have been produced that possess essentially no catalytic activity or cytotoxicity, but that maintain native conformation and elicit a protective immune response when used as an immunogen. These recombinant noncytotoxic forms of pertussis toxin have been engineered with multiple mutations in their active site, virtually eliminating the risk of reversion to a cytotoxic form. Similar strategies are being applied to other bacterial exotoxins with the goal of engineering acellular vaccine candidates.

IV. THERAPEUTIC APPLICATIONS OF EXOTOXINS

One of the most exciting areas of bacterial exotoxin research has been the development of strategies to use exotoxins in therapeutic disciplines. Some therapies use the native cytotoxic form of the exotoxin. Other therapies use either the **A** or **B** domain, which is conjugated to a heterologous binding component or to effector elements, respectively, to produce a chimeric molecule with directed properties.

Botulinum toxin and tetanus toxin (BT/TT) are each a single protein that is organized as an **AB** exotoxin. The amino terminus of BT/TT expresses endopeptidase activity and constitutes the **A** domain, whereas the **B** domain possesses neuronal cell-specific receptor-binding activity. The specific association of the **B** domain with neuronal cells is responsible for the clinical manifestation of these neurotoxins. BT/TT appear to enter neuronal cells by receptor-mediated endocytosis and to deliver the **A** domain to the cytosol, where it catalyzes the endoproteolytic cleavage of host proteins that are involved in vesicle fusion. Studies have shown that botulinum toxin can be introduced into the muscles surrounding the eye to temporarily reduce muscle spasms associated with several clinical disorders.

Diphtheria toxin has been used as a carrier to stimulate an immune response against several epitopes. One epitope is polyribitolphosphate, a component of the polysaccharide capsule of *Haemophilus influenzae* type b

(Hib). Early attempts to elicit an effective immune response to purified Hib antigen resulted in the production of a T-cell-independent immune response that did not yield an effective memory. A noncatalytic mutant of diphtheria toxin, CRM197, has been used as a carrier for the Hib epitope. Immunization with the CRM197-Hib conjugate yielded a strong T-dependent immune response. Mass immunization with Hib conjugates has resulted in a dramatic reduction in the number of cases of Hib in the immunized population.

Due to their potency, the catalytic **A** domain of exotoxins have been used in the construction of chimeric immunotoxins that are designed to target cancer cells. Early studies used conjugates that were composed of the **A** domain of the diphtheria toxin coupled to an antibody that recognized a cell surface-specific antigen. The **A** chain of the diphtheria toxin was used in the first generation of immunotoxins because it had been shown to possess impressive cytotoxic potential when introduced into the cytosol of eukaryotic cells. It was estimated that the introduction of a single molecule of the **A** chain of diphtheria toxin into the cytosol was sufficient to kill that cell. In cell culture, these chimera have proven to be both potent and antigen specific. Ongoing research involves the determination of clinical situations for the use of these chimeras in a therapeutic arena.

The **B** component of anthrax toxin, protective antigen (PA) and a truncated, non-cytotoxic form of one of its **A** components (LF) has recently been used to deliver epitopes into antigen presenting cells to elicit a cytotoxic lymphocyte (CTL) response. Anthrax toxin is a tripartite toxin composed of three non-associated proteins. After binding to cells, PA is proteolytically processed and undergoes oligomerization to form a heptameric structure on the cell surface. Processed PA is able to bind either LF or edema factor (EF) and the **AB** complex undergoes receptor-mediated endocytosis in which acidification in the early endosome stimulates the translocation of the **A** domain into the cell cytosol. In the nontoxic anthrax delivery system, PA is added to antigen-presenting cells with a nontoxic LF-CTL epitope chimera used to deliver the epitope into the host cell for antigen presentation. One of the more attractive aspects of this CTL-epitope delivery system is that small amounts of PA are required to present antigen.

V. OTHER CLASSES OF BACTERIAL TOXINS

A. Pore-forming toxins

The lack of a catalytic **A** domain differentiates the pore-forming toxins from exotoxins. Thus, the pathology

associated with pore-forming toxins is due solely to the generation of a pore within the membrane of the host cell. Several bacterial pathogens produce pore-forming toxins, some of which are secreted by a type I secretion pathway. Unlike type II-secreted proteins, the amino terminus of type I-secreted proteins is not processed. Type I-secreted proteins possess a polyglycine signal sequence in the carboxyl terminus of the mature toxin. There are several classes of pore-forming toxins, including members of the hemolysin family of pore-forming toxins, the aerolysin family of pore-forming toxins, and the α -toxin of *Staphylococcus aureus*. Host-cell specificity differs among pore-forming toxins. The crystal structures of several of the pore-forming toxins have been determined. The molecular events generating a pore in the membrane of a host cell have been proposed for the aerolysin family of pore-forming toxins. Aerolysin is exported by *Aeromonas hydrophila* as a monomeric molecule, which binds to the host cell. The monomer is pro-teolytically processed and subsequently undergoes oligomerization. The oligomerized complex is inserted into the membrane and generates a pore in the center of the complex, causing the release of the cytoplasmic components of the host cell.

B. Type III-secreted cytotoxins

The lack of a **B** domain differentiates the type III-secreted cytotoxins from exotoxins. Thus, the organization of the type III-secreted cytotoxins may be represented as **A** domains that are specific effector proteins. Type III-secreted cytotoxins are transported directly into the host cells by cell surface-bound bacteria. Type III secretion of bacterial proteins is a recently defined pathway for the delivery of proteins into the cytoplasm of host cells. Type III-secreted proteins were initially recognized by the fact that the secreted mature cytotoxins were unique to proteins secreted by either the type I or II secretion pathways, whereas the amino terminus of type III-secreted proteins is not processed nor is there a polyglycine motif in their carboxyl terminus. Although it is clear that a complete type III secretion apparatus is required for the transport of type III-secreted proteins into the host cytoplasm, the mechanism for the delivery of type III-secreted proteins across the host-cell membrane remains to be resolved. Numerous bacteria have been shown to possess type III secretion pathways, including members of the genera *Escherichia*, *Pseudomonas*, *Shigella*, *Salmonella*, and *Yersinia*. Cytotoxicity elicited by type III-secreted cytotoxins has an absolute

requirement for the type III secretion apparatus of the bacterium, as purified forms of the cytotoxins are not toxic to host cells.

The A domains of type III-secreted cytotoxins catalyze several unique mechanisms of action, including the depolymerization of the actin cytoskeleton, phosphatase activity, ADP-ribosyltransferase activity, and the stimulation of apoptosis. Each type III secretion apparatus appears capable of delivering numerous type III-secreted proteins into the host cell.

C. Heat-stable enterotoxins

The inability of the heat-stable enterotoxins to enter the host cell or possess catalytic activity differentiates the heat-stable enterotoxins from exotoxins. Several genera of bacteria produce heat-stable enterotoxins, including *Escherichia* and *Yersinia*. The heat-stable enterotoxin a (STa) of *E. coli* is the prototype toxin of this group. *E. coli* secretes STa into the periplasm as a 72-amino-acid precursor in which three intramolecular disulfide bonds are formed and processed into a 53-amino-acid form. The 53-amino-acid form of STa is exported into the environment, where a second proteolytic cleavage results in the production of an 18- or 19-amino-acid mature STa molecule. The mature STa binds to a protein receptor on the surface of epithelial cells, which results in an increase in the intracellular concentrations of cGMP. The intracellular increase in cGMP results in a stimulation of chloride secretion and net fluid secretion, resulting in diarrhea.

D. Superantigens

The inability of superantigens to enter the host cell or possess catalytic activity differentiates the superantigens from exotoxins. Superantigens are soluble proteins of approximately 30 kDa that are secreted by bacteria that possess mitogenic properties. Superantigens are produced by both *Streptococcus* and *Staphylococcus*. The superantigens bind to a component of the major histocompatibility complex of T lymphocytes through an antigen-independent mechanism, which stimulates proliferation of a large subset of T lymphocytes.

Extremophiles

Ricardo Cavicchioli and Torsten Thomas

University of New South Wales

GLOSSARY

alkaliphile An organism with optimal growth at pH values above 10.

Archaea One of the three domains (highest taxon) of life, evolutionarily distinct from the Bacteria and Eucarya (eukaryotes).

autotroph An organism able to use CO₂ as a sole source of carbon.

barophile An organism that lives optimally at high hydrostatic pressure.

chemolithotroph An organism obtaining its energy from the oxidation of inorganic compounds.

chemoorganotroph An organism obtaining its energy from the oxidation of organic compounds. Also referred to as a heterotroph.

extreme acidophile An organism with a pH optimum for growth at or below pH 3.

extremophile An organism that is isolated from an extreme environment and often requires the extreme condition for growth ("extreme" is anthropocentrically derived).

growth optimum The conditions (e.g., temperature and salinity) at which an organism grows fastest.

halophile An organism requiring at least 0.2M salt for growth.

hyperthermophile An organism having a growth temperature optimum of 80°C or higher.

methanogen An archaeal microorganism that produces methane.

mixotroph An organism able to assimilate organic compounds as carbon sources and use inorganic compounds as electron donors.

oligotroph An organism with optimal growth in nutrient-limited conditions.

phototroph An organism that obtains energy from light.

phylogeny The ordering of species into higher taxa and the construction of evolutionary trees based on evolutionary relationships rather than on general resemblances.

prokaryote A cell or organism lacking a nucleus and other membrane-enclosed organelles, usually having its DNA in a single circular molecule. Loosely used to describe archaeal and bacterial microorganisms in contrast to eukaryotic microorganisms.

psychrophile An organism having a growth temperature optimum of 15°C or lower, and a maximum temperature of 20°C or lower.

Extremophiles are organisms that require extreme environments for growth. Although this is perhaps self-evident, what constitutes extreme? Extreme is a relative term, with the point of comparison being what is normal for humans. Extremophiles are therefore organisms that are "fond of" or "love" (-phile) environments such as high temperature, pH, pressure, or salt concentration; or low temperature, pH, nutrient concentration, or water availability. Extremophiles are also organisms that can tolerate other extreme conditions, including high levels of radiation or toxic compounds, or living conditions that humans consider unusual, such as living in rocks 1.5 km below the surface of Earth. In addition, extremophiles may be found in environments with a combination of extreme conditions, such as high temperature and high acidity or high pressure and low temperature.

I. INTRODUCTION

Most extremophiles are microorganisms. For example, the upper temperature limits for archaeal, bacterial, and eukaryotic microorganisms are 113, 95, and 62°C, respectively, in contrast to most metazoans (multicellular eukaryotes, e.g., animals and plants), which are unable to grow above temperatures of 50°C. This example of thermal adaptation highlights an important distinction among the different classes of microorganisms (i.e., Archaea can grow at extremely high temperatures in comparison to their eukaryotic counterparts), and underscores the fundamentally different evolutionary origins of the members of the three domains of life, Archaea, Bacteria, and Eucarya. Although Archaea (formerly Archaeobacteria) and Bacteria are both loosely defined as prokaryotes, they are by no means more similar to each other than Archaea are to eukaryotes. For example, archaea have a number of archaeal-specific traits (glycerol-1-phosphate–lipid backbones and methanogenesis), in addition to sharing many bacterial (metabolism, biosynthesis, energy generation, transport, and nitrogen fixation) and eukaryotic (transcription, translation, and replication) features. Due to the fact that Archaea are often found in extreme environments, the term “extremophile” is often used synonymously with “archaea”, and many of the extremophiles described here are members of the Archaea. It should be noted, however, that Archaea are also found in a broad range of nonextreme marine and soil environments.

The first use of the term “extremophile” appeared in 1974 in a paper by MacElroy (*Biosystems* 6: 74–75) entitled, “Some Comments on the Evolution of Extremophiles.” In the 1990s, studies on extremophiles have progressed to the extent that the First International Congress on Extremophiles was convened in Portugal, June 2–6, 1996, and the scientific journal *Extremophiles* was established in February 1997. These developments in the field have arisen due to the isolation of extremophiles from environments previously considered impossible

for sustaining biological life. As a result, the appreciation of microbial biodiversity has been reinvigorated and challenging new ideas about the origin and evolution of life on Earth have been generated. In addition, the novel cellular components and pathways identified in extremophiles have provided a burgeoning new biotechnology industry.

In recognition of the importance of extremophiles to microbiology, the following sections describe the habitats, biochemistry, and physiology of a diverse range of extremophiles, followed by a concluding section on the biotechnological applications of extremophiles and their products.

II. HYPERTHERMOPHILES

A. Defining temperature classes of microorganisms

Microorganisms can generally be separated into four groups with regard to their temperature optima for growth. In order of increasing temperature, they are psychrophiles (optimum of 15°C, maximum <20°C), mesophiles (optimum between 20 and 45°C), thermophiles (optimum between 45 and 80°C), and hyperthermophiles (optimum of 80°C or higher). On the whole, these definitions are generally accepted terms; the reader should be aware, however, that some terms may have alternative meanings in specific fields. For example, the upper temperature for the growth of yeast is about 48°C, and the majority of yeasts can grow below 20°C. As a result, a thermophilic yeast is defined by its inability to grow below 20°C, but with no restrictions placed on the maximum temperature for growth.

B. Habitats and microorganisms

Hyperthermophiles have been isolated from a range of natural geothermally heated environments (Table 37.1). The terrestrial environments tend to be acidic (as low

TABLE 37.1 Examples of locations where hyperthermophiles have been isolated

Geography	Type of habitat	Location
Terrestrial	Hot springs	US, New Zealand, Iceland, Japan, Mediterranean, Indonesia, Central America, Central Africa
Subterranean	Oil reservoir (3500 m)	North Sea, North Alaska
Submarine	Shallow depth (beaches)	Italy, Sao Michel (the Azores), Djibouti (Africa)
	Sea mounts	Tahiti
	Moderate depth (120 m)	mid-Atlantic Ridge (north of Iceland)
	Deep sea (>1000 m)	Guaymas Basin (2000 m) and East Pacific Rise (2500–2700 m) (both near Mexico), mid-Atlantic Ridge (3600–3700 m), mid-Okinawa Trough (1400 m), Galapagos Rift

as pH 0.5) with low salinity (0.1–0.5% salt), whereas the marine systems are saline (3% salt) and generally less acidic (pH 5–8.5). Artificial sources of isolates include coal refuse piles and geothermal power plants.

The terrestrially based, volcanic systems include hot springs such as solfataras, which are sulfur-rich and generally acidic, or others that are boiling at a neutral pH, or that are iron-rich. Most of the heated soils and water contain elemental sulfur and sulfides, and most isolates metabolize sulfur. A by-product of oxidation tends to be sulfuric acid and as a result many of the hot springs are extremely acidic. Hyperthermophilic archaea have also been isolated from oil from geothermally heated oil reserves present in Jurassic sandstone and limestone 3500 m below the bed of the North Sea and below the Alaskan North Slope permafrost soil. As a by-product of their metabolism during oil extraction, they produce hydrogen sulfide; this condition is referred to as reservoir souring.

Numerous hyperthermophiles have been isolated from submarine hydrothermal systems, including hot springs, sediments, sea mounts (submarine volcanoes), fumaroles (steam vents with temperatures up to 150–500°C), and deep-sea vents. The hot deep-sea vents are often referred to as “black smokers” due to the thick plume of black material that forms from mineral-rich fluids at temperatures up to 400°C, precipitating on mixing with the cold (1–5°C) seawater. The submarine systems are a rich source of microbial and higher eukaryotic life that spans the temperature ranges suitable for hyperthermophiles through psychrophiles. Due to the extreme depth of some of the vents (3500 m), organisms are also exposed to extreme pressure, and as a result they tend to be barophilic or barotolerant (see Section V).

The tube worms, giant clams, and mussels that inhabit the vents are dependent on the activity of the chemolithotrophic microorganisms to fix CO₂ and use a broad range of inorganic energy sources emitted from the vents. The first eukaryotic organism living at very high temperatures was identified at the Axial Summit Caldera, west of Mexico. The Pompeii worm (*Alvinella pompejana*) was observed living in a hydrothermal system in which the posterior of the worm was in 80°C water. Interestingly, it is speculated that the ability of the worm to survive the heat may be due to the presence of microorganisms that cover its exterior and secrete heat-stable enzymes.

Most isolated hyperthermophiles are members of Archaea, and it is this characteristic that is often associated with this class of microorganism. However, it was the isolation of *Thermus aquaticus*, a bacterium, from a hot spring in Yellowstone National Park by Thomas Brock in 1969 that led to the discoveries of

hyperthermophilic archaea. In 1972, Brock described *Sulfolobus*, an obligately aerobic archaeon that is able to oxidize H₂S or S⁰ to H₂SO₄ and fix CO₂ as a carbon source. The hot springs that *Sulfolobus* spp. thrive in are typically as hot as 90°C, with an acidity of pH 1–5. Some hyperthermophiles have been found in unique locations, for example, *Methanothermus* spp., which have only been isolated from one solfataric area of Iceland. In contrast, *Pyrococcus* and *Thermococcus* spp. have been found in both submarine systems and subterranean oil reserves. Of all the isolates to date, *Pyrolobus fumarii* has the highest maximum temperature (113°C). Furthermore, it is restricted to temperatures above 90°C. Using a microscope slide suspended in the outflow from a black smoker at 125–140°C, microbial films have been detected on the glass surfaces. Although organisms capable of growth at such high temperatures have not been isolated, this is good evidence that microorganisms are capable of growth in this extreme temperature range.

C. Biochemistry and physiology of adaptation

A broad diversity of hyperthermophiles with varied morphologies, metabolisms, and pH requirements have been isolated, and the characteristics of a number of these are shown in Table 37.2. Although organisms such as *Sulfolobus* spp. are aerobic chemoorganotrophs, most hyperthermophiles are anaerobic and many are chemolithotrophs. The extent of metabolic diversity in the hyperthermophiles is exemplified by the strict requirement of *Methanococcus jannaschii* for CO₂ and H₂ only, in comparison to the broad spectrum of substrates used as electron donors by the sulfate-reducing archaeon, *Archaeoglobus fulgidus*, including H₂, formate, lactate, carbohydrates, starch, proteins, cell homogenates, and components of crude oil. This indicates that there are no particular carbon-use or energy-generation pathways that are exclusively linked to growth at high temperatures.

For any microorganism, lipids, nucleic acids, and proteins are all generally susceptible to heat, and there is, in fact, no single factor that enables all hyperthermophiles to grow at high temperatures.

1. Membrane lipids and cell walls

Archaeal lipids all contain ether-linkages (as opposed to the ester-linkages in most bacteria), which provide resistance to hydrolysis at high temperature. Some hyperthermophilic archaea contain membrane-spanning, tetra-ether lipids that provide a monolayer type of organization that gives the membranes a high

TABLE 37.2 Characteristics of selected hyperthermophiles^a

Genus	Minimum temperature	Optimum temperature	Maximum temperature	DNA		Aerobe (+) Anaerobe (-)	Energy yielding reactions	Morphology

^aAll are archaeal species unless otherwise indicated. Data from Madigan, M. T., Martinko, J. M., and Parker, J. (1997). *Brock: Biology of Microorganisms*, 8th Ed. Prentice Hall; Stetter, K. O. (1998). Hyperthermophiles: Isolation, classification and properties. In "Extremophiles: Microbial Life in Extreme Environments" (K. Horikoshi, and W. D. Grant, Eds.), Wiley series in Ecological and Applied Microbiology, Wiley-Liss.

degree of rigidity and may confer thermal stability. The bacterium *Thermotoga maritima* also contains a novel ester lipid, which may increase stability at high growth temperatures. However, the archaeon *Methanopyrus kandleri*, which can grow at up to 110°C, contains unsaturated diether lipids that resemble terpenoids, and it is unclear how this may affect the thermal resistance of the cell. Lipid composition also varies with the growth temperature of individual organisms. For example, in *Methanococcus jannaschii* at 45°C, 80% of the lipid content is one lipid (archaeol), whereas at 75°C, two lipids (caldarchaeol and macrocyclic archaeol) account for 80% of the total core.

Most archaeal species possess a paracrystalline surface layer (S-layer) consisting of protein or glycoprotein. It is likely that the S-layer functions as an external protective barrier. In *Pyrodictium* spp., the highly irregularly shaped, flagellated cells are interconnected by extracellular glycoprotein tubules that remain stable at 140°C.

2. Nucleic acids

The thermal resistance of DNA could conceivably be improved by maintaining a high mol% G + C content;

however, many hyperthermophiles have between 30 and 40% (Table 37.2), in comparison to, for example, the mesophile *Escherichia coli*, which has 50%. *Acidianus infernus* has a G + C content of 31%, which would rapidly lead to the melting of double-stranded DNA at its optimum growth temperature of 90°C. Histone-like proteins that bind DNA have been identified in archaeal hyperthermophiles. It is likely that the DNA is protected by the histones and that this enables processes such as open-complex formation during transcription to occur without subsequent DNA melting. In addition, hyperthermophiles contain reverse gyrase, a type 1 DNA topoisomerase that causes positive supercoiling and therefore may stabilize the DNA.

3. Proteins and solutes

Heat-shock proteins, including chaperones, are likely to be important for stabilizing and refolding proteins as they begin to denature. When *Pyrodictium occultum* is heat-stressed at 108°C, 80% of total protein accumulated is a single chaperonin, termed the "thermosome," the cells' protein-folding machine. In addition to the differential expression of certain genes throughout the growth temperature range of the organism, proteins

from hyperthermophiles are inherently more stable than those from thermophiles, mesophiles, or psychrophiles. Higher stability is a result of increased rigidity (decreased flexibility) of the protein. Certain structural properties favor a more rigid protein (see psychrophilic proteins in Section IV.B.2), including a higher degree of structure in hydrophobic cores, an increased number of hydrogen bonds and salt bridges, and a higher proportion of thermophilic amino acids (e.g., proline residues that have fewer degrees of freedom). As a result, the proteins from hyperthermophiles are extremely heat stable. For example, proteases from *Pyrococcus furiosus* have half-lives of >60 h at 95°C and an amylase from *Pyrococcus woessii* is active at 130°C.

Protein stability may also be assisted by the accumulation of intracellular potassium and solutes, such as 2,3-diphosphoglycerate (cDPG). In *Methanopyrus kandleri* and *Methanothermus fervidus*, there is evidence that potassium is required for enzyme activity at high temperature and the potassium salt of cDPG acts as a thermal stabilizer.

D. Evolution

Earth is about 4.6 billion years old and life is believed to have evolved on Earth around 3.6–4 billion years ago. The atmosphere of early Earth was devoid of oxygen and contained gaseous H₂O, CH₄, CO₂, N₂, NH₃, HCN, trace amounts of CO and H₂, and large quantities of H₂S and FeS. For the first 0.5 billion years, the surface of the planet was probably devoid of water because the temperature was higher than 100°C. Subsequently, the planet cooled and water liquefied. The high temperatures imply that life evolving in these conditions must have possessed thermophilic properties. Due to the high temperature and the available carbon and energy substrates, a microorganism such as H₂-oxidizing sulfur-reducing *Methanopyrus kandleri* would conceivably thrive.

Studying the phylogenetic relationship of extant (living) microorganisms by the analysis of 16S-ribosomal ribonucleic acid (16S-rRNA) sequences, reveals that the hyperthermophilic Archaea and Bacteria have short evolutionary branches that occur near the base of the tree of life. Short branches indicate a low rate of evolution and deep branches reflect a close relationship with primordial life forms. This suggests that hyperthermophiles living today may resemble some of the earliest forms of life on Earth.

There is some evidence that microbial life may have existed (or still exists) on Mars and other terrestrial bodies (e.g., on Europa, one of Jupiter's moons). In association with the characteristics of hyperthermophiles mentioned, this has led to the

consideration that life on Earth may have originated from the introduction of extraterrestrial life. A possible scenario involves a meteor carrying microbial life similar to hyperthermophilic methanogens plunging into the ocean billions of years ago and initiating the use of inorganic matter to generate biological matter and the subsequent evolution of extant species. These possibilities are driving new research endeavors to discover extraterrestrial life (see Section IV.A on psychrophiles and lakes on Europa).

III. EXTREME ACIDOPHILES

A. Habitats and microorganisms

An extreme acidophile has a pH optimum for growth at or below pH 3.0. This definition excludes microorganisms that are tolerant to pH below 3, but that have pH optima closer to neutrality, including many fungi, yeast, and bacteria (e.g., the ulcer- and gastric-cancer causing gut bacterium *Helicobacter pylori*).

1. Natural environments

Extremely acidic environments occur naturally and artificially. The hyperthermophilic extreme acidophiles *Sulfolobus*, *Sulfurococcus*, *Desulfurolobus*, and *Acidianus* produce sulfuric acid in solfataras in Yellowstone National Park from the oxidation of elemental sulfur or sulfidic ores. Other members of the Archaea found in these hot environments include species of *Metallosphaera*, which oxidize sulfidic ores, and *Stygiolobus* spp., which reduce elemental sulfur. The novel, cell-wall-less archaeon, *Thermoplasma volcanium*, which grows optimally at pH 2 and 55°C, has also been isolated from sulfotatic fields around the world. The bacterium *Thiobacillus caldus* has been isolated in hot acidic soils. *Bacillus acidocaldarius*, *Acidimicrobium ferrooxidans*, and *Sulfobacillus* spp. have also been isolated from warm springs and hot spring runoff.

The most extreme acidophiles known are species of Archaea, *Picrophilus oshimae* and *Picrophilus torridus*, which were isolated from two solfataric locations in northern Japan. One of the locations, which contained both organisms, is a dry soil, heated by solfataric gases to 55°C and with a pH of less than 0.5. These remarkable species have aerobic heterotrophic growth with a temperature optimum of 60°C and a pH optimum of 0.7 (i.e., growth in 1.2 M sulfuric acid).

In addition to Archaea, the phototrophic red alga *Galdieria sulphuraria* (*Cynadium caldarium*), isolated in cooler streams and springs in Yellowstone National

Park, has optimum growth at pH of 2–3 and 45 °C, and is able to grow at pH values around 0. The green algae *Dunaliella acidophila* is also adapted to a narrow pH range from 0 to 3.

2. Artificial environments

The majority of extremely acid environments are associated with the mining of metals and coal. The microbial processes that produce the environments are a result of dissimilatory oxidation of sulfide minerals, including iron, copper, lead, and zinc sulfides. This process can be written as $\text{Me}^{2+}\text{S}^{2-}$ (insoluble metal complex) \rightarrow $\text{Me}^{2+} + \text{SO}_4^{2-}$; where Me represents a cationic metal. As a result of the extremely low pH in these environments, and due to the geochemistry of the mining sites, cationic metals (e.g., Fe^{2+} , Zn^{2+} , Cu^{2+} , and Al^{3+}) and metalloid elements (e.g., arsenic) are solubilized; this process is referred to as microbial ore leaching.

Most mining sites tend to have low levels of organic compounds, and as a result chemolithoautotrophs, such as the bacteria *Thiobacillus ferrooxidans*, *Thiobacillus thiooxidans*, *Leptospirillum ferrooxidans*, and *Leptospirillum thermoferrooxidans*, are prolific. In addition, mixotrophic *Thiobacillus cuprinus* and heterotrophic *Acidiphilium* spp. have been isolated from acidic coal refuse and mine drainage. Thermophilic acidophilic bacterial species include *Thiobacillus caldus* from coal refuse, *Acidimicrobium ferrooxidans* from copper-leaching dumps, and *Sulfobacillus* spp. from coal refuse and mine water. The archaeal microorganism *Thermoplasma acidophilum* is frequently isolated from coal refuse piles. Coal refuse contains coal, pyrite (an iron sulfide), and organic material extracted from coal. As a result of spontaneous combustion, the refuse piles are self-heating and provide the thermophilic environment necessary for sustaining *Thermoplasma* and other thermophilic microorganisms.

In illuminated regions (e.g., mining outflows and tailings dams), phototrophic algae, including *Euglena*, *Chlorella*, *Chlamydomonas*, *Ulothrix*, and *Klebsormidium* species, have been isolated. Other eukaryotes include species of yeast (*Rhodotorula*, *Candida*, and *Cryptococcus*), filamentous fungi (*Acontium*, *Trichosporon*, and *Capnospodium*) and protozoa (*Eutreptia*, *Bodo*, *Cinetochilium*, and *Vahlkampfia*).

B. Biochemistry and physiology of adaptation

Acidophiles (and alkaliphiles; see Section VII) keep their internal pH close to neutral. Most extreme acidophiles maintain an intracellular pH above 6, and

even *Picrophilus* maintains an internal pH of 4.6 when the outside pH is 0.5–4. As a result, extreme acidophiles have a large chemical proton gradient across the membrane. Proton movement into the cell is minimized by an intracellular net positive charge and as a result cells have a positive inside-membrane potential. This is caused by amino acid side chains of proteins and phosphorylated groups of nucleic acids and metabolic intermediates, acting as titratable groups. In effect, the low intracellular pH leads to protonation of titratable groups and produces a net intracellular positive charge. In addition to this passive effect, some acidophiles (e.g., *Bacillus coagulans*) produce an active proton-diffusion potential that is sensitive to agents that disrupt the membrane potential, such as ionophores.

The ability of lipids from the archaeon *Picrophilus oshimae* to form vesicles is lost when the pH is neutral, thus indicating that the membrane lipids are adapted for activity at low pH to minimize proton permeability. In *Dunaliella acidophila*, the surface charge and inside membrane potential are both positive, which is expected to reduce influx of protons into the cell. In addition, it overexpresses a potent cytoplasmic membrane H^+ -ATPase to facilitate proton efflux from the cell.

The pH to which a protein is exposed affects the dissociation of functional groups in the protein and may be affected by salt and solute concentrations. Few periplasmic surface-exposed or -secreted proteins from extreme acidophiles have been studied to identify the structural features important for activity and stability. In *Thiobacillus ferrooxidans*, the acid stability of rusticyanin (acid-stable electron carrier) has been attributed to a high degree of inherent secondary structure and the hydrophobic environment in which it is located in the cell. A relatively low number of positive charges have been linked to the acid stability of secreted proteins (thermopsin, a protease from *Sulfolobus acidocaldarius*, and an α -amylase from *Alicyclobacillus acidocaldarius*), by minimizing electrostatic repulsion and protein unfolding.

IV. PSYCHROPHILES

A. Habitats and microorganisms

Over 80% of the total biosphere of Earth is at a temperature permanently below 5 °C, and it is therefore not surprising that a large number and variety of organisms have adapted to cold environments. These natural environments include cold soils; water (fresh and saline, still and flowing); in and on ice in polar or alpine regions; polar and alpine lakes, and sediments;

caves; plants, and cold-blooded animals (e.g. Antarctic fish). Artificial sources include many refrigerated appliances and equipment.

Organisms thriving in low-temperature environments (0°C or close to 0°C) are commonly classified as psychrophilic or psychrotolerant. Psychrophiles (cold-loving) grow fastest at a temperature of 15°C or lower, and are unable to grow over 20°C. Psychrotolerant (also termed psychrotrophic) organisms grow well at temperatures close to the freezing point of water; however, their fastest rates of growth are above 20°C. Psychrophilic and psychrotolerant microorganisms include bacteria, archaea, yeast, fungi, protozoa, and microalgae.

It is generally found that psychrophiles predominate in permanently cold, stable environments that have good sources of nutrition (e.g., old, consolidated forms of sea ice exposed to algal blooms). It is likely that the permanency of the cold in stable environments obviates the need for cells to be able to grow at higher temperatures. In addition, at low temperature the affinity of uptake and transport systems decrease, and as a result, psychrophiles tend to be found in environments that are rich in organic substrates, thus providing compensation for less effective uptake and transport systems.

1. Natural environments

Psychrophiles have been isolated from permanently cold, deep-ocean waters, as well as from ocean sediments as deep as 500 m below the ocean floor. As a consequence of the pressure in these environments, many of these psychrophiles are also barotolerant or barophiles (see Section V).

A unique source of cold-adapted microorganisms are lakes in the Vestfold Hills region in Antarctica. The Vestfold Hills lakes are only about 10,000 years old and differ in their salinity and ionic strength, oxygen content, depth, and surface ice coverage. As a result, they have proven to be a rich resource of diverse and unusual microorganisms, including a cell-wall-less Spirochaete, a coiled or "C-shape" bacterium, and the only known free-living, psychrophilic archaeal species. The archaeal species include the methanogens *Methanococcoides burtonii* and *Methanogenium frigidum*, and the extreme halophile *Halobacterium lacusprofundi*. The only other low-temperature-adapted archaeal isolate that has been studied is the symbiont *Cenarchaeum symbiosum*, which was isolated from a marine sponge off the Californian coast. It is perhaps surprising that more low-temperature-adapted Archaea have not been isolated throughout the world, as 16S-rRNA analysis of numerous aquatic and soil samples have

indicated the prevalence of Archaea in these cold habitats.

Gram-negative bacteria, including members of the genera *Pseudomonas*, *Achromobacter*, *Flavobacterium*, *Alcaligenes*, *Cytophaga*, *Aeromonas*, *Vibrio*, *Serratia*, *Escherichia*, *Proteus*, and *Psychrobacter* are more frequently found in cold environments than are gram-positive bacteria (e.g. *Arthrobacter*, *Bacillus*, and *Micrococcus*). Psychrophilic yeast are of the genera *Candida* and *Torulopsis*, and psychrotolerant members are mostly of the genera *Candida*, *Cryptococcus*, *Rhodotorula*, *Torulopsis*, *Hanseniaspora*, and *Saccharomyces*. Low-temperature-adapted fungi and molds include isolates of the genera *Penicillium*, *Cladosporium*, *Phoma*, and *Aspergillus*. The most common snow alga is *Chlamydomonas nivalis*, which produces bright red spores, marking its location clearly against the white snow background.

A remarkable, and as yet unstudied, low-temperature environment has been discovered in Antarctica. Lake Vostok is a subglacial lake found about one kilometer below Vostok Station, East Antarctica. More than sixty smaller subglacial lakes also exist in central regions of the Antarctic Ice Sheet. Due to the isolation of the lakes, they are likely to contain many novel microorganisms, some of which could be expected to have developed along a separate evolutionary path from that of currently known life. The exploration of Lake Vostok is being considered using specialized robots based on thermal-probe technology for ice penetration, and submersible technology for lake exploration. Interestingly, the ocean on Europa (a moon of Jupiter) is also located below a kilometer-thick covering of ice. The technology developed for Lake Vostok will be a model for future exploration (in 2003–2018) of the ocean on Europa and provides the unprecedented potential to identify extraterrestrial life in an aquatic environment.

2. Artificial environments

The abundance of microorganisms in cold environments was realized as early as 1887, when the first low-temperature-adapted bacterium was probably isolated from a preserved fish stored at 0°C. Since then, numerous psychrotolerant organisms have been found in artificial habitats and are frequently responsible for the spoilage of food. Members of the genera *Pseudomonas*, *Acinetobacter*, *Alcaligenes*, *Chromobacterium*, and *Flavobacterium* are often associated with spoilage of dairy products, whereas *Lactobacillus viridescens* and *Brochothrix thermospacta* contaminate meat products. Psychrotolerant bacterial pathogens include

Yersinia enterocolitica, *Clostridium botulinum*, and certain *Aeromonas* strains.

B. Biochemistry and physiology of adaptation

Unicellular organisms are unable to insulate themselves against low temperatures and, as a consequence, psychrophilic and psychrotolerant microorganisms need to adapt the structures of their cellular components.

1. Membranes

It is well documented that microorganisms adjust the fatty acid composition of their membrane phospholipids in response to changes in the growth temperature. Normal cell function requires membrane lipids that are largely fluid. As temperature is decreased, the fatty acids chains in membrane bilayers undergo a change of state from a fluid disordered state to a more ordered crystalline array of fatty acid chains. In order to adapt to low temperature, microorganisms decrease the transition temperature of the disordered-to-ordered state by altering the fatty acyl composition. This alteration consists of one or a combination of the following changes to the membrane lipids: an increase in unsaturation, a decrease in average chain length, an increase in methyl branching, an increase in the ratio of *anteiso*-branching compared to *iso*-branching, and an isomeric alteration of acyl chains in *sn-1* and *sn-2* positions. The most common alterations occur in fatty acid saturation and chain length. Changes in the amount and type of methyl-branching occur mostly in gram-positive bacteria. Most bacteria only have monosaturated fatty acids; however a notable exception was found in some marine psychrophilic bacteria that increase membrane fluidity at low temperatures by incorporating polyunsaturated fatty acids into their membranes.

Alterations in the membrane lipid composition can be mediated in a rapid fashion through the increase of unsaturation catalyzed by desaturases. Changes in fatty acyl chain length and the amount and type of methyl branching, however, require *de novo* fatty acid synthesis and are therefore much slower processes.

2. Enzymes

The thermodynamic problems associated with enzymes in an environment of low kinetic energy (i.e., low temperature) relate to the lack of sufficient energy to achieve the activation state for catalysis. Low-temperature adaptation of proteins therefore lowers the free energy of the activated state by decreasing the enthalpy-driven interactions necessary for activation.

The necessity for weaker interactions leads to a less rigid, more flexible protein structure, or parts thereof. Consequently, factors that confer a more "loose" or flexible structure are expected to be important for cold-adapted proteins. Based on the comparison of proteins from low-temperature-adapted Bacteria, Archaea, and Eukarya with those from mesophiles to hyperthermophiles, including comparisons of three-dimensional structures, a number of structural differences have been identified; including the reduction of the number of salt bridges, the reduction of aromatic interactions, the reduction of hydrophobic clustering, the reduction of proline content, the addition of loop structures, and an increase in solvent interaction. It should be noted that no cold-adapted protein has been studied that exhibits all of these features. This highlights the importance of the molecular context of the changes to stability, activity, or both. As a general rule, however, enzymes from psychrophilic organisms have reduced thermostability and a lower apparent temperature optima for their activity when compared to their mesophilic or thermophilic counterparts.

3. Cold shock and cold acclimation

The response to a rapid decrease in temperature (cold shock) has been well studied in mesophilic laboratory microorganisms, including *Escherichia coli*, *Bacillus subtilis*, and *Saccharomyces cerevisiae*. In response to cold shock, the pattern of gene expression is altered (cold-shock response). In bacteria, a class of small (7–8 kDa) acidic proteins are transiently induced. These cold-shock proteins (CSPs) have been well characterized and shown, in some cases, to function as transcriptional enhancers and RNA-binding proteins. In *S. cerevisiae*, TIP1 (temperature-shock-inducible protein 1) is a major CSP; it is targeted to the outside of the plasma membrane and appears to be heavily glycosylated with *O*-mannose, therefore invoking a role for TIP1 in membrane protection during low-temperature adaptation. Following a cold shock, cells resume growth, albeit at a lower growth rate, indicating that the cold-shock response is an adaptive response aimed at maintaining growth, rather than a stress response aimed only at cell survival.

In general, the process of protein synthesis is temperature sensitive. As a result, psychrophilic microorganisms must have specially adapted ribosomes and accessory factors (e.g., initiation and elongation factors). In addition, psychrophilic and psychrotolerant microorganisms (particularly those that are food-borne) may be exposed to sudden changes in their environmental temperature. A cold-shock response has been demonstrated in a number of

psychrophilic and psychrotolerant organisms, including *Trichosporon pullulans*, *Bacillus psychrophilus*, *Aquaspirillum arcticum*, and *Arthrobacter globiformis*; and homologs of a major *E. coli* cold-shock protein (CspA) have been identified in a number of these. The extent of the response (i.e., the number of proteins induced) in these microorganisms is dependent on the magnitude of the temperature shift. Some of the CSPs are also cold-acclimation proteins (proteins expressed continuously during growth at low temperature), suggesting that this class of CSP is important for cold-shock adaptation and growth maintenance at low temperatures.

V. BAROPHILES

A. Habitats and microorganisms

Barophiles (“weight lovers”) are organisms that thrive in high-pressure habitats. An etymologically more accurate term is “piezophiles” (“pressure lovers”); however, it is less frequently used in the literature.

There is apparent confusion and contradiction in the literature concerning the defining traits of pressure-adapted organisms. This mainly stems from the complicating effects of temperature on growth rate. The effect of both temperature (T) and pressure (P) on the growth rate (k) of different organisms has been thoroughly investigated using “PTk-diagrams.” With all other conditions held constant, there is a unique pressure, $P_{k_{\max}}$, and temperature, $T_{k_{\max}}$, at which the growth rate of an individual microorganism is maximal (k_{\max}). These values have been used to define barophiles with $P_{k_{\max}} > 0.1$ MPa and extreme barophiles with $P_{k_{\max}} \leq 0.1$ MPa. In addition, the values for $T_{k_{\max}}$ have been used to delineate psychro-, meso-, or thermo- (extreme) barophiles. Other terms used are obligate (extreme) barophiles, for organisms that cannot grow at atmospheric pressure (0.1 MPa), irrespective of temperature, and barotolerants, for those that grow best under atmospheric pressure but that can also grow at up to 40 MPa.

Barophiles were first isolated from the deep sea (deeper than 1000 m), and this environment still represents the most thoroughly studied habitat. Other high-pressure habitats include the deep-Earth and the deep-sediment layers below the ocean floor. The deep sea is a cold ($<5^{\circ}\text{C}$), dark, oligotrophic (low in nutrients) environment with pressure as high as 110 MPa, as is found in the Mariana Trench (almost 11,000 m). In contrast, fumarole and black-smoker hydrothermal vents, produced by the extrusion of hot subsurface water, represent a hyperthermal environment with

high metabolic activity (see hyperthermophiles in Section II). The microbiota of Atlantic and Pacific vents are remarkably similar, indicating that the (hyper-) thermobarophilic microorganisms are able to survive for long periods in cold waters, thus facilitating their effective dispersal throughout the oceans. Supporting this, these microorganisms have been isolated from ocean waters far removed from hydrothermal vents.

Psychrophilic deep-sea (extreme) barophilic isolates predominantly belong to five genera of the γ -Proteobacteria—*Photobacterium*, *Shewanella*, *Colwellia*, *Moritella*, and a new group containing the strain CNPT3. One *Bacillus* species (strain DSK25) has also been isolated. Hyperthermobarophilic archaeal isolates include *Pyrococcus* spp. It is noteworthy that the difficulty in isolating microorganisms from the deep sea, and the specific enrichment and culturing techniques that are used, are likely to produce a bias in the types of barophiles that are isolated; a complete analysis of the phylogenetic distribution of barophilic microorganisms is yet to be attempted.

B. Biochemistry and physiology of adaptation

1. General physiological adaptations

Membrane lipids from barophilic bacteria have been well studied. In response to high pressure, the relative amount of monounsaturations and polyunsaturations in the membrane is increased. The increase in unsaturation produces a more fluid membrane and counteracts the effects of the increase in viscosity caused by high pressure. This response is analogous to adaptations caused by temperature reduction (see Section IV). Note, however, that an increase in unsaturation was not observed in two extreme barophiles that have been studied, thus indicating that alternative mechanisms of adaptation exist.

An interesting observation for many barophiles is that they are extremely sensitive to UV light and need to be grown in dark or light-reduced environments. This adaptation is not unexpected, considering the darkness that prevails in the deep sea.

There are presently no studies on barophilic microorganisms investigating the adaptation of molecular processes such as chromosomal replication, cell division, transcription, or translation. Studies of *E. coli*, however, have revealed that when cells are grown at their upper pressure limit, DNA synthesis is completely inhibited, protein synthesis is slowed down, and mRNA synthesis and decay appears to be unaffected. This demonstrates that specific cellular processes are affected by pressure, and therefore barophiles are likely to have adapted mechanisms to

compensate. Pressure may stabilize proteins and retard thermal denaturation. In support of this, thermal inactivation of DNA polymerases from the hyperthermophilic microorganisms *Pyrococcus furiosus*, *Pyrococcus* strain ES4, and *Thermus aquaticus* is reduced by hydrostatic pressure.

2. Gene and protein expression

Pressure-regulated gene and protein expression has been observed and investigated in deep-sea bacteria. *Photobacterium* sp. SS9 expresses two outer-membrane proteins (porins) under different pressures, the OmpH protein at 28 MPa and OmpL at 0.1 MPa. The genes are regulated by a homolog of the *toxRS* system from *Vibrio cholerae*. ToxR and ToxS are cytoplasmic membrane proteins that are thought to be pressure sensors controlled by membrane fluidity.

A pressure-regulated operon has been identified in the barophilic bacterium DB6705. A complex promoter region, which is controlled by a variety of regulatory proteins expressed under different pressure conditions, was identified upstream of three open reading frames (ORFs). The function of the first two ORFs is unknown, while the third ORF encodes the CydD protein. CydD is required for the assembly of the cytochrome-bd complex in the aerobic respiratory chain. The membrane location of this protein highlights the apparent importance of membrane components in high-pressure adaptation.

probably dates to 2500 BC, when the Chinese noted a red coloration of saturated salterns. What they detected was most likely a bloom of extreme halophilic Archaea that possess red or orange C₅₀ carotenoides.

The definition of a hypersaline environment is one that possesses a salt concentration greater than that of seawater (3.5% w/v). For water-containing environments, the salt composition depends greatly on the historical development of the habitat, and the environments are normally described as thalassohaline or athalassohaline. Thalassohaline waters are marine derived and therefore contain, at least initially, a seawater composition; however, with increasing evaporation the concentration of various salts alters depending on the thresholds for the crystallization and precipitation of different minerals (see Table 37.3). Athalassohaline water may also be influenced by the influx of seawater; however, the chemical composition is mainly determined by geological, geographical, and topographical parameters. Examples of athalassohaline environments include the Great Salt Lake in Utah and the Dead Sea.

In addition to lakes formed by evaporation in moderate climate conditions, hypersaline Antarctic lakes (e.g., Vestfold Hills; see Section IV) have been formed from the effects of frost and dryness in this environment. Antarctic and moderate temperature soils also contain salinities between 10 and 20% (w/v) and efforts have been directed at characterizing these comparatively poorly studied ecosystems. Less obvious saline habitats known to be colonized by microorganisms are animal skins, plant surfaces, and building surfaces. In addition, interest is also being focused on subterranean salt deposits as a habitat for extreme halophilic Archaea, and as a possible source of ancient prokaryotic lineages preserved in fluid inclusion bodies of salt crystals.

VI. HALOPHILES

A. Habitats and microorganisms

The first recorded observation of organisms adapted to high salt concentrations (halophiles and halotolerants)

TABLE 37.3 Concentration of ions in thalassohaline and athalassohaline brines^a

Ion	Concentration (g/l)					
	Seawater	Seawater at onset of NaCl saturation	Seawater at onset of K ⁺ -salt saturation	Great Salt Lake	Dead Sea	Typical soda lake
Na ⁺	10.8	98.4	61.4	105.0	39.7	142
Mg ²⁺	1.3	14.5	39.3	11.1	42.4	<0.1
Ca ²⁺	0.4	0.4	0.2	0.3	17.2	<0.1

TABLE 37.4 Defining terms for microorganisms ranging in tolerances to salt

Category	Salt concentration (M)	
	Range	Optimum
Nonhalophilic	0–1.0	<0.2
Slightly halophilic	0.2–2.0	0.2–0.5
Moderate halophilic	0.4–3.5	0.5–2.0
Borderline extreme halophilic	1.4–4.0	2.0–3.0
Extreme halophilic	2.0–5.2	>3.0
Halotolerant	0–1.0	<0.2
Haloversatile	0–3.0	0.2–0.5

Organic compounds in hypersaline lakes are mostly produced by cyanobacteria, anoxygenic phototrophic bacteria, and by species of the green algae *Dunaliella* spp. They are found in most natural and artificial hypersaline lakes around the world. With seasonal and transient contributions from animals or plants, these environments can contain dissolved organic carbon levels up to 1 g/l. Due to the low solubility of oxygen in saline solutions, however, many habitats become anaerobic and as a result aerobic growth is often restricted to the upper layers.

Organisms living in saline habitats exhibit different levels of adaptation to salt. To account for the variety of tolerances, an extensive set of definitions exist and are summarized in Table 37.4.

A salt concentration of about 1.5M is the upper limit for vertebrates, although some eukaryotes such as the brine shrimp (*Artemia salina*) and the brine fly (*Ephedra*) can be found in habitats with higher salinity. For salinities above 1.5M, prokaryotes become the predominant group with moderate halophilic and haloversatile bacteria at salt concentrations between 1.5 and 3.0M, and extreme halophilic Archaea (halobacteria) at salinities around the point of sodium chloride precipitation.

Aerobic gram-negative chemoorganotrophic bacteria are abundant in brines of medium salinity, and many strains have been isolated, including members of the genera *Vibrio*, *Alteromonas*, *Acinetobacter*, *Deleya*, *Marinomonas*, *Pseudomonas*, *Flavobacterium*, *Halomonas*, and *Halovibrio*. Gram-positive aerobic bacteria of the *Marinococcus*, *Sporosarcina*, *Salinococcus* and *Bacillus* species have been found in saline soils, salterns, and occasionally in solar salterns. Members of the genera *Halomonas* and *Flavobacterium* have been isolated from Antarctic lakes. Two of the most remarkable isolates from Antarctica are the extreme halophilic archaeal species *Halobacterium lacusprofundi* and a *Dunaliella* spp., which are found in association in Deep Lake. These are the only two microorganisms growing in this lake, which has 4.8M salt and whose temperature for 8 months of the year is less than 0°C. With the

extremes of temperature, salt, and ionic strength, and with primary production rates of 10° g C/m²/year, Deep Lake has been described as one of the most inhospitable environments on Earth.

Wherever light reaches the anoxic layer of hypersaline brines, anoxygenic phototrophs such as *Chromatium salexigens*, *Thiocapsa halophila*, *Rhodospirillum salinarum*, and *Ectothiorhodospira* are commonly found and represent the primary producers in these environments. Sulfate reducers *Desulfovibrio halophilus* and *Desulfohalobium retbaense* have been isolated from anaerobic sediments and are thought to perform dissimilatory sulfate reduction to H₂S. H₂S is subsequently used for growth by most anoxygenic phototrophs (except for members of the *Rhodospirillaceae* family). Anaerobic fermentative halophiles from the bacterial lineage of *Haloanaerobiaceae* have also been described.

Most of the bacterial species mentioned here are predominant in environments up to 2M salt. At higher concentrations, extremely halophilic Archaea (including the confusingly named genus, *Halobacteria*) are more abundant. Most of these Archaea require at least 1.5M salt for growth and for retaining their structural integrity. Members of the genera *Haloarcula*, *Halobacterium*, and *Halorubrum* are frequently found in hypersaline waters reaching the sodium chloride saturation point, and the proteolytic species *Halobacterium salinarium* is often associated with salted food. Other Archaea are also found in saline lakes, marine stromatolites, and solar ponds, and these tend to be methanogens (see Section X). In addition, the eukaryote *Dunaliella* can adapt to a wide range of salt concentrations, from less than 100 mM to saturation (5.5M).

B. Biochemistry and physiology of adaptation

Cells exposed to an environment with a higher salinity than the one inside the cytoplasm inevitably experience a loss of water and undergo plasmolysis (Fig. 37.1). Microorganisms living in high-salt environments generally adopt one of two strategies (either salt-in-cytoplasm or compatible-solute adaptation) to prevent the loss of cytoplasmic water and to establish osmotic equilibrium across their cell membranes.

1. Salt-in-cytoplasm adaptation

Extremely halophilic archaea and anaerobic halophilic bacteria use a salt-in-cytoplasm strategy. This involves cations flowing through the membrane into the cytoplasm (Fig. 37.1A). Archaea accumulate intracellular potassium and exclude sodium, whereas Bacteria accumulate sodium rather than potassium. As a consequence of the high salt, intracellular

components (e.g., proteins, nucleic acid and cofactors) require protection from the denaturing effects of salt. The most common protective mechanism is the presence of excess negative charges on their exterior surfaces. Malate dehydrogenase from *Haloarcula marismortui* has a 20 mol% excess of acidic residues over basic amino acid residues, compared to only 6 mol% excess for a nonhalophilic counterpart. Structural analysis shows that the acidic residues are mainly located on the surface of the protein and are either involved in the formation of stabilizing salt bridges or in attracting water and salt to form a strong hydration shell. This malate dehydrogenase is able to bind extraordinary amounts of water and salt (0.8–1.0 g water and 0.3 g salt/g protein) compared to a nonhalophilic malate dehydrogenase (0.2–0.3 g water and 0.01 g salt/g protein). Due to the adaptation mechanism in these cells, they have an obligate requirement for high concentrations of salt. In low-salt environments,

FIGURE 37.1 Effect of high salinity on intracellular water, and two strategies used for adaptation. Solid circles represent salt molecules and open circles compatible solutes.

the lack of salt removes the shielding effect of cations from the proteins and leads to the rapid denaturation of the three-dimensional structure.

2. Compatible-solute adaptation

Most halotolerant and moderately halophilic organisms, including the anoxygenic phototrophic bacteria, aerobic heterotrophic bacteria, cyanobacteria, and methanogens, maintain a salt-minimized cytoplasm. They accumulate small organic and osmotically active molecules, referred to as compatible solutes. These compounds can be synthesized *de novo* or imported from the surrounding medium (Fig. 37.1b). The latter mechanism is also used by nonhalophilic organisms; they adapt to increased salt concentrations by importing extracellular compatible solutes using transporters involved in amino acid or sugar uptake.

A large range of compatible solutes has been identified in a broad range of halophiles (Table 37.5). All these molecules are polar, highly soluble, and uncharged or zwitterionic at physiological pH values. They are strong water-structure formers and as such are probably excluded from the hydration shell of proteins (preferential exclusion), and therefore exert a stabilizing effect without interfering directly with the structure of the protein. In addition to being stabilizers against salt stress, they have also been shown to prevent the denaturation of proteins caused by heating, freezing, and drying.

3. Membranes

Even though the cytoplasmic interior is protected from the effects of external salt by cytoplasmic-compatible

TABLE 37.5 Compatible solutes used by halophilic microorganisms

Class of compatible solute	Specific compatible solute	Microorganism
Polyols	Glycerol and arabite	Algae, yeast, fungi
Betaines	Glucosyl-glycerol	Cyanobacteria
	Glycine-betaine	Cyanobacteria, anoxygenic phototrophic bacteria, methanogens and <i>Actinopolyspora halophila</i>
Amino acids	Dimethylglycine	<i>Methanohalophilus</i> sp.
	Proline	<i>Bacillus</i> spp. and other <i>Firmicutes</i>
	α -glutamine	Corynebacteria
	β -glutamine	<i>Methanohalophilus</i> sp
Dimethylsulfiopropionate		Marine cyanobacteria
Glutamine amides	<i>N</i> - α -carbomoyl-glutamine amide	<i>Ectothiorhodospira marismortui</i>
	<i>N</i> - α -acetyl-glutaminy-glutamine amide	Anoxygenic phototrophic proteobacteria, <i>Rhizobium meliloti</i> , and <i>Pseudomonas</i> spp.
Acetylated diamino acids	<i>N</i> - δ -acetyl-ornithine and <i>N</i> - ϵ -acetyl- α -lysine	<i>Bacillus</i> spp. and <i>Sporosarcina halophila</i>
Ectoines	<i>N</i> - ϵ -acetyl- α -lysine	Methanogens
	Ectoine and hydroxyectoine	Proteobacteria, <i>Brevibacteria</i> , gram-positive cocci, and <i>Bacillus</i> spp.

solutes, the outer surface of the cytoplasmic membrane is permanently exposed to high salt concentrations. To protect the membrane in halophilic bacteria, the proportion of anionic phospholipids (often phosphatidylglycerol and glycolipids) increases with increasing salinity at the expense of neutral zwitterionic phospholipids. These alterations produce additional surface charges to the membrane and help to maintain the hydration state of the membrane.

Most halophilic Archaea possess an S-layer consisting of sulfated glycoproteins, which surrounds the cytoplasmic membrane. The sulfate groups confer a negative charge to the S-layer and possibly provides structural integrity at high ionic concentrations. In addition, archaeal ether lipids have been shown to be more stable at high salt concentrations (up to 5M) compared to the ester lipids found in the membranes of bacteria.

VII. ALKALIPHILES

A. Habitats and microorganisms

Alkaliphiles are defined by optimal growth at pH values above 10, whereas alkalitolerant microorganisms may grow well up to pH 10, but exhibit more rapid growth below pH 9.5. Alkaliphiles are further subdivided into facultative alkaliphiles (that grow well at neutral pH) and obligate alkaliphiles (that grow only above pH 9). In addition, due to their natural habitats, many alkaliphilic organisms are adapted to high salt concentrations and are referred to as haloalkaliphiles.

Alkali environments include soils where the pH has been increased by microbial ammonification and sulfate reduction, and water derived from leached silicate minerals. These environments tend to have only a limited buffering capacity and the pH of the environments fluctuates. As a result, alkalitolerant microorganisms are more abundant in these habitats than are alkaliphiles. Artificial environments include locations of cement manufacture, mining, and paper and pulp production. Probably the best studied and most stable alkaline environments are soda lakes and soda deserts (e.g., in the East African Rift Valley or central Asia). The formation of soda lakes and deserts is similar to the formation of athalassohaline salt lakes (see Section V), with the exception that carbonate is the major anion in solution, due to the lack of divalent cations (Mg^{2+} , Ca^{2+}) in the surrounding environment. A typical soda lake composition is shown in Table 37.2.

Bacteria, Archaea, yeast, and fungi have been isolated from alkali environments. Archaeal alkaliphiles include members of the *Halobacteriaceae* (*Halorubrum*, *Natronbacterium*, and *Natronococcus* spp.) and

Methanosarcinaceae (*Methanohalophilus* spp.). Cyanobacterial genera *Spirulina* and *Synechococcus* represent the dominant primary producers in the aerobic layers of soda lakes. Other alkaliphilic bacteria are members of the *Actinomyces*, *Bacillaceae*, *Clostridiaceae*, *Haloanaerobiales*, and γ -Proteobacteria (*Ectothiorodospira*, *Halomonadaceae*, and *Pseudomonas*). Anaerobic thermophilic alkaliphiles (alkalithermophiles) include *Clostridium* and *Thermoanaerobacter* spp., and the only representative of a new taxon, *Thermopallium natronophilum*.

B. Biochemistry and physiology of adaptation

1. pH homeostasis

Studies of alkaliphiles (particularly *Bacillus* spp.) have demonstrated that they maintain a neutral or slightly alkaline cytoplasm. This is reflected by a neutral pH optimum for intracellular enzymes compared to a high pH optimum for extracellular enzymes. The intracellular pH regulation has been shown to be dependent on the presence of sodium. The Na^+ ions are exchanged from the cytoplasm into the medium by H^+/Na^+ antiporters (Fig. 37.2). Electrogenic proton extrusion is mediated in aerobic cells by respiratory chain activity and protons are transported back into the cell via antiporters that are efficient at transporting H^+ into the cell at the expense of Na^+ export from the cell. The resulting net production and influx of protons creates a more acidic cytoplasm. In addition to controlling protons, Na^+ -dependent pH homeostasis requires the reentry of Na^+ into the cell. Na^+ -coupled solute symporter and sodium-driven flagella rotation ensure a net sodium balance. The combined action of the antiporters coupled with respiration provides the cell with a means to control its internal pH while maintaining sufficient Na^+ levels through symport and flagella rotation.

FIGURE 37.2 Schematic representation of elements involved in pH homeostasis in alkaliphilic microorganisms. R represents respiratory chain-mediated proton translocation; NhaC and NhaJ represent two separate H^+/Na^+ antiporters found in *Bacillus* spp.; S represents a Na^+ -dependent solute transporter; and F represents Na^+ -dependent flagella motility.

The exterior surfaces of the cell are also important for maintaining a pH differential. This is supported by evidence that the protoplasts of alkaliphilic *Bacillus* spp. are unstable in alkaline conditions. The peptidoglycan in these strains has a higher cross-linking rate at higher pH values, which may provide a shielding effect by "tightening" the cell wall. Large amounts of acidic compounds, including teichuronic acid, teichoic acid, uronic acids, and acidic amino acids, are evident in alkaliphilic cell walls compared to the cell walls of nonalkaliphilic microorganisms. The negative charge of these acidic substances may create a more neutral layer close to the outer surface of the cell.

2. Bioenergetics

Alkaliphiles have unique bioenergetic properties. Nonalkaliphilic respiring bacteria energize their cytoplasmic membrane with a chemiosmotic driving force (Δp) by generating an electrochemical gradient of ions that has two parameters—acidic conditions outside (caused by the extrusion of protons and described by the term ΔpH) and a positive charge outside (described by the transmembrane electrical potential, $\Delta \Psi$). The Δp is used for proton-coupled symport of solutes, proton-driven mobility (flagella) and ATP synthesis. In alkaliphilic environments, the contribution of ΔpH to Δp becomes smaller with increasing extracellular pH. However, with increasing extracellular pH, sodium ion export is increased (see Section VII.B.1) and may contribute to an increased $\Delta \Psi$. This partially compensates for the decrease of Δp by the reduction of ΔpH . Interestingly, the sodium gradient is used to energize solute transport and flagella movement, but not for ATP synthesis. No sodium-dependent ATP-synthases have been identified in alkaliphiles. In addition, ATP-synthases in alkaliphilic *Bacillus* spp. have been shown to be exclusively proton translocating.

VIII. OLIGOTROPHS

A. Habitats and microorganisms

A most important environmental factor in microbial ecology is the availability of energy, and virtually all microbial cells in nature are limited in their growth by the availability of one or more essential growth nutrients. For example, in the intestinal tract, the number of *E. coli* doubles about twice per day, whereas in ideal laboratory conditions it doubles in 20 min. Similarly, soil bacteria are estimated to grow in soil at about 1% of the maximal rate of growth observed in the laboratory. This highlights that in natural ecosystems nutrient limitation is the rule, rather than the exception.

In addition to the overall nutrient status, in aquatic and soil environments, nutrient levels are often transient; for example, a fallen leaf provides nutrients to soil microorganisms, or a dead fish provides nutrients in an aquatic environment. As a result of this apparent "feast or famine," microorganisms have adopted two main strategies for surviving in nutrient-depleted (oligotrophic) environments. Eutrophic microorganisms (also referred to as copiotrophs, saphrophytes, and heterotrophs) grow in bursts when nutrients are available and produce resting-stage cells when nutrients are in short supply (referred to as r-strategy). In contrast, oligotrophic microorganisms (also referred to as oligocarbophiles; low-nutrient, LN, bacteria; low- K_s bacteria; and dilute-nutrient-broth, DNB, organisms) grow slowly, using low concentrations of nutrients (referred to as K-strategy).

It is important to note that whereas oligotrophs grow slowly in oligotrophic environments, eutrophs are in a resting stage. In contrast, when members of these two classes are subcultured from oligotrophic environments into rich media, the eutrophs resume rapid growth, whereas the oligotrophs do not grow at all. The cellular responses that prevent growth of the oligotrophs in rich media is not understood; however, the response highlights the physiological differences between these two classes of microorganisms. In addition, the difficulty in growing oligotrophs in the laboratory has proven problematic for examining their physiology. Fortunately, some isolates have adapted (facultative oligotrophs) to growth in rich media and are amenable to laboratory studies.

Although the definition of an oligotroph and an oligotrophic environment remain the subject of debate, it is generally accepted that an oligotroph is able to grow in a medium containing 0.2–16.8 mg dissolved organic carbon/liter. The terms "obligate oligotroph" (implying the inability to grow in high concentrations of nutrients) and "facultative oligotroph" (indicating the ability to grow in low and high concentrations of nutrients) are also used to further clarify the nutritional requirements for growth.

In natural ecosystems, oligotrophs and eutrophs coexist, and the proportion of each varies depending on their individual abilities to dominate in the particular environment. For example, when the marine oligotrophic ultramicrobacterium *Sphingomonas* sp. strain RB2256 was isolated from Resurrection Bay, Alaska, it was a numerically dominant species in a place where the total bacterioplankton population was 0.2–1.07 $\times 10^6$ cells/ml. In contrast, significantly lower numbers (<1%) of larger, faster-growing cells (typical of eutrophs) were able to be immediately cultured in rich media and on plates.

B. Biochemistry and physiology of adaptation

A characteristic that is often associated with oligotrophic bacteria is their ultramicro size ($<0.1 \mu\text{m}^3$). Ultramicrobacteria (or dwarf cells) are commonly found in aquatic and soil environments. Oligotrophic ultramicrobacteria, such as *Sphingomonas* RB2256, retain their ultramicro size irrespective of growth phase, carbon source, or carbon concentration. In contrast, eutrophic microorganisms, such as *Vibrio angustum* S14 and *Vibrio* ANT-300, undergo reductive cell division during starvation, but resume their normal size ($>1 \mu\text{m}^3$) when grown in rich media.

The characteristics that are thought to be important for oligotrophic microorganisms include a substrate uptake system that is able to acquire nutrients from its surroundings, and the capacity to use the nutrients in order to maintain its integrity and growth. As a result, oligotrophs would ideally have large surface-area-to-volume ratios, and high-affinity uptake systems with broad substrate specificities. Consistent with this, a number of microorganisms that are adapted to low-nutrient environments produce appendages to enhance their surface area. These include members of the bacterial genera, *Caulobacter*, *Hyphomicrobium*, *Prosthecomicrobium*, *Ancalomicrobium*, *Labrys*, and *Stella*. Other bacteria have tiny cell volumes (ultramicrobacteria: $<0.1 \mu\text{m}^3$) to maximize their surface-area-to-volume ratio.

The most comprehensive physiological studies of oligotrophic marine isolates have been performed on *Sphingomonas* sp. strain RB2256. The characteristics that distinguish it from typical marine eutrophs include constant ultramicro size irrespective of growth or starvation conditions, a mechanism for avoiding predation (ultramicro size), a relatively slow maximum specific growth rate ($<0.2 \text{h}^{-1}$), a single copy of the rRNA operon compared to 8–11 copies for *Vibrio* spp., a relatively small genome size compared to faster-growing heterotrophs, an ability to use low concentrations of nutrients, high-affinity broad-specificity uptake systems, an ability to simultaneously take up mixed substrates, an ability to immediately respond to nutrient addition without a lag in growth, and an inherent resistance to environmental stresses (e.g., heat, hydrogen peroxide, and ethanol).

The small ($0.2 \mu\text{m}^3$) oligotrophic bacterium *Cycloclasticus oligotrophicus* RB1, which was also isolated from Resurrection Bay, shares some properties similar to *Sphingomonas* RB2256 (e.g., single copy of the rRNA operon, and relatively small cell size and genome size). Interestingly, while this chemoorganotroph is unable to grow using glucose and amino acids, it can use acetate and a few aromatic hydrocarbons such as toluene.

IX. RADIATION-RESISTANT MICROORGANISMS

A. Habitats and microorganisms

Radiation from the sun drives photosynthetic reactions, thus ensuring primary production throughout the global ecosystem. Although the visible spectrum leads to biomass production, visible light and other portions of the electromagnetic spectrum (particularly short-wavelength) also cause cellular damage. Damage to cells primarily occurs directly to nucleic acids (e.g., UV-induced thymine-dimer formation and strand breakage) or indirectly through the production of reactive oxygen species (e.g., H_2O_2 , O_2^- , ^0OH , and $^1\text{O}_2$), which cause damage to lipids, proteins, and nucleic acids. Due to the prevalence of natural radiation, most cells have developed a range of DNA-repair and other protective mechanisms to facilitate their survival.

In contrast to natural forms of relatively low-level radiation, microorganisms may be exposed to intense sources of radiation in the form of γ -irradiation (^{60}Co and ^{137}Cs) as a means of sterilization or by being in close proximity to nuclear reactors. It is mainly these forms of radiation that have been the sources of highly radiation-resistant extremophiles. The most well-studied of these is the bacterium *Deinococcus radiodurans*, which was first isolated in 1956 from tins of meat that had been irradiated with γ -rays. Although some microorganisms escape radiation damage by forming spores (e.g., *Clostridium botulinum*), *D. radiodurans* is resistant while in the exponential growth phase. The degree of resistance of these cells is illustrated by their ability to survive 3,000,000 rad, a dose that is sufficient to kill most spores (a lethal dose for humans is about 500 rad). As a consequence of the extreme radiation resistance of *D. radiodurans* and other microorganisms, biocides are routinely added to the cooling waters of nuclear reactors to prevent the proliferation of microorganisms. By virtue of their resistant properties, this class of extremophile can be readily isolated by exposing samples to intense UV or γ -irradiation and then plating them out on a rich medium.

Although *Deinococcus* spp. have been found in dust, processed meats, medical instruments, textiles, dried food, animal feces, and sewage, their natural habitats have not been clearly defined. Thermophilic species have, however, been isolated from hot springs in Italy, and deinococci have been identified in many soil environments. It therefore appears that this class of radiation resistant extremophiles exists in a broad range of environmental niches.

In addition to *Deinococcus* spp., some hyperthermophilic Archaea (e.g., *Thermococcus stetteri* and

Pyrococcus furiosus) are able to survive high levels of γ -irradiation.

B. Biochemistry and physiology of adaptation

Resistance to radiation could conceivably occur by two main mechanisms, prevention of damage or efficient repair of damage. In *D. radiodurans*, it has been clearly shown that the DNA is severely damaged during γ -irradiation (e.g., ~110 double-strand breaks per cell when exposed to 300,000 rad); however, within 3 h of recovery, the fragmented DNA is replaced by essentially intact, chromosomal DNA. Furthermore, even though the DNA within the cells has been extensively degraded, viability is unaffected. *P. furiosus* is also able to repair fragmented DNA after exposure to 250,000 rad when the cells are grown at 95°C. As a result, it has been suggested that active DNA-repair mechanisms may be important determinants of survival of hyperthermophiles in their natural environments.

In addition to γ -radiation resistance, *D. radiodurans* is resistant to highly mutagenic chemicals, with the exception of those that cause DNA deletions (e.g., nitrosoguanidine, NTG). *D. radiodurans* is also extremely resistant to UV irradiation, surviving doses as high as 1000 J/m². The dose that is required to inactivate a single colony-forming unit of an irradiated population is for *D. radiodurans* 550–600 J/m² compared to just 30 J/m² for *E. coli*.

The DNA-repair systems in *D. radiodurans* are so effective that they have proven to be a hindrance for genetic studies, that is, it is difficult to isolate stable mutants. However, through the combined use of chemical mutagenesis and screens for mitomycin C-, UV radiation-, and ionizing radiation-sensitive strains, genes involved in nucleotide-excision repair, base-excision repair, and recombinational repair have been identified. In addition, *D. radiodurans* is multigenomic (e.g., there are 2.5–10 copies of the chromosome depending on growth rate) and a novel mechanism of interchromosomal recombination has been proposed. This process would help to circumvent problems of reassembling a complete and contiguous chromosome from the chromosome fragments that have been generated as a result of irradiation. It appears that *D. radiodurans*'s ability to use its genome multiplicity to repair DNA damage is the most fundamental reason for this species's extraordinary radioresistance.

Almost all *Deinococcus* spp. that have been isolated (even those isolated without selection for radiation resistance) are radiation resistant, thus demonstrating that the extreme resistance is not a result of selection by irradiation, but a normal characteristic of the genus. Desiccation leads to DNA damage in all cells and

prevents DNA repair from occurring. For a cell to be viable when it is rehydrated, it needs to be able to repair the damaged DNA. It is therefore likely that the evolutionary process that has led to the inherent radiation resistance in *Deinococcus* is natural selection for resistance to desiccation. This is supported by evidence that *D. radiodurans* is also exceptionally resistant to desiccation.

X. OTHER EXTREMOPHILES

As a group, methanogenic Archaea (methanogens) are often considered extremophiles. They are the most thermally diverse organisms known, inhabiting environments from close to freezing in Antarctic lakes to 110°C in hydrothermal vents. Those isolated from Antarctica include *Methanococcoides burtonii* and *Methanogenium frigidum*, and those from hydrothermal vents include *Methanopyrus kandleri*, *Methanothermus fervidus*, *Methanothermus sociabilis*, *Methanococcus jannaschii*, and *Methanococcus igneus*. Methanogens can also be isolated from a diverse range of salinities, from fresh water to saturated brines. *Methanohalobium evestigatum* was isolated from a microbial mat in Sivash Lake and grows in pH neutral, hypersaline conditions from 2.6–5.1 M. Alkaliphilic (*Methanosalsus zhilinaeae*, pH 8.2–10.3) and acidophilic (*Methanosarcina* sp., pH 4–5) methanogens have also been isolated.

Other microorganisms that may be considered to be extremophiles include toxitolerants (those tolerant to organic solvents, hydrocarbons, and heavy metals, such as *Rhodococcus* sp., which can grow on benzene as a sole carbon source), and xerophiles and xerotolerant microbes that survive very low-water activity (e.g., extremely halophilic Archaea, fungi such as *Xeromyces bisporus*, and endolithic microorganisms that live in rocks).

XI. BIOTECHNOLOGY OF EXTREMOPHILES

A major impetus driving research on extremophiles is the biotechnological potential associated with the microorganisms and their cellular products. In 1992, of the patents related to Archaea, about 60% were for methanogens, 20% for halophiles, and 20% thermophiles. Examples of "extremozymes" that are presently used commercially include alkaline proteases for detergents. This is a huge market, with 30% of the total worldwide enzyme production for detergents. In 1994, the total market for alkaline proteases in Japan alone was ~15,000 million yen. DNA polymerases have been isolated from the hyperthermophiles *Thermus aquaticus*, *Thermotoga maritima*, *Thermococcus litoralis*,

TABLE 37.6 Extremophiles and their uses in biotechnology

Source	Use
Hyperthermophiles	
DNA polymerases	DNA amplification by PCR
Alkaline phosphatase	Diagnostics
Proteases and lipases	Dairy products
Lipases, pullulanases, and proteases	Detergents
Proteases	Baking and brewing and amino acid production from keratin
Amylases, α -glucosidase, pullulanase, and xylose/glucose isomerases	Starch processing, and glucose and fructose for sweeteners
Alcohol dehydrogenase	Chemical synthesis
Xylanases	Paper bleaching
Lenthionin	Pharmaceutical
S-layer proteins and lipids	Molecular sieves
Oil degrading microorganisms	Surfactants for oil recovery
Sulfur oxidizing microorganisms	Bioleaching, coal, and waste gas desulfurization
Hyperthermophilic consortia	Waste treatment and methane production
Psychrophiles	
Alkaline phosphatase	Molecular biology
Proteases, lipases, cellulases, and amylases	Detergents
Lipases and proteases	Cheese manufacture and dairy production
Proteases	Contact-lens cleaning solutions, meat tenderizing
Polyunsaturated fatty acids	Food additives, dietary supplements
Various enzymes	Modifying flavors
β -galactosidase	Lactose hydrolysis in milk products
Ice nucleating proteins	Artificial snow, ice cream, other freezing applications in the food industry
Ice minus microorganisms	Frost protectants for sensitive plants
Various enzymes (e.g., dehydrogenases)	Biotransformations
Various enzymes (e.g., oxidases)	Bioremediation, environmental biosensors
Methanogens	Methane production
Halophiles	
Bacteriorhodopsin	Optical switches and photocurrent generators in bioelectronics
Polyhydroxyalkanoates	Medical plastics
Rheological polymers	Oil recovery
Eukaryotic homologues (e.g., <i>myc</i> oncogene product)	Cancer detection, screening antitumor drugs
Lipids	Liposomes for drug delivery and cosmetic packaging
Lipids	Heating oil
Compatible solutes	Protein and cell protectants in a variety of industrial uses (e.g., freezing, heating)
Various enzymes (e.g., nucleases, amylases, proteases)	Various industrial uses (e.g., flavoring agents)
γ -linoleic acid, β -carotene and cell extracts (e.g., <i>Spirulina</i> and <i>Dunaliella</i>)	Health foods, dietary supplements, food coloring, and feedstock
Microorganisms	Fermenting fish sauces and modifying food textures and flavors
Microorganisms	Waste transformation and degradation (e.g., hypersaline waste brines contaminated with a wide range of organics)
Membranes	Surfactants for pharmaceuticals
Alkaliphiles	
Proteases, cellulases, xylanases, lipases and pullulanases	Detergents
Proteases	Gelatin removal on X-ray film
Elastases, keritinas	Hide dehairing
Cyclodextrins	Foodstuffs, chemicals, and pharmaceuticals
Xylanases and proteases	Pulp bleaching
Pectinases	Fine papers, waste treatment, and degumming
Alkaliphilic halophiles	Oil recovery
Various microorganisms	Antibiotics
Acidophiles	
Sulfur-oxidizing microorganisms	Recovery of metals and desulfurization of coal
Microorganisms	Organic acids and solvents

Pyrococcus woessii, and *Pyrococcus furiosus* for use in the polymerase chain reaction (PCR). A eukaryotic homolog of the *myc* oncogene product from halophilic Archaea has been used to screen the sera of cancer patients. Its utility is demonstrated by the fact that the archaeal homolog produced a higher number of positive reactions than the recombinant protein expressed in *E. coli*. β -carotene is commercially produced from the green algae *Dunaliella bardawil*. The applications in industry are still limited; however, the potential applications are extensive. Some examples of their uses and potential applications are listed in Table 37.6.

The biotechnology potential is increasing exponentially with the isolation of new organisms, the identification of novel compounds and pathways, and the molecular and biochemical characterization of cellular components. Major advances are likely in the area of protein engineering. For example, the identification of the structural properties important for thermal activity and stability will enable the construction of proteins with required catalytic and thermal properties. Recently, a metalloprotease from the moderately thermophilic bacterium *Bacillus stearothermophilus* was mutated using a rational design process in an effort to increase its thermostability. The mutant protein was 340 times more stable than the wild-type protein and was able to function at 100°C in the presence of denaturing agents, while retaining wild-type activity at 37°C.

Advances are also likely to arise from the construction of recombinant microorganisms for specific purposes. A recombinant strain of *Deinococcus radiodurans* has been engineered to degrade organopollutants in radioactive mixed-waste environments. The recombinant *Deinococcus* expresses toluene dioxygenase, enabling it to oxidize toluene, chlorobenzene, 2,3-dichloro-1-butene, and indole in a highly irradiating environment (6000 rad/h), while remaining tolerant to the solvent effects of toluene and trichloroethylene at levels exceeding those of many radioactive waste sites. In recognition of the number of waste sites contaminated with organopollutants plus radionuclides and heavy metals around the world, and the safety hazards and cost involved in clean up using physicochemical means, the potential use of genetically engineered extremophilic microorganisms is an important and exciting prospect.

Fimbriae, Pili

Matthew A. Mulvey, Karen W. Dodson, Gabriel E. Soto, and Scott J. Hultgren

Washington University School of Medicine

GLOSSARY

curli A class of thin, irregular, and highly aggregated adhesive surface fibers expressed by *Escherichia coli* and *Salmonella enteritidis*.

periplasmic chaperones A class of proteins localized in the periplasm of gram-negative bacteria that facilitates the folding and assembly of pilus subunits, but which are not components of the final pilus structure.

phase variation The reversible on-and-off switching of a bacterial phenotype, such as pilus expression.

pilin The individual protein subunit of a pilus organelle (also known as a fimbrin). Immature pilins, containing leader signal sequences that direct the transport of pilins across the inner membrane of gram-negative bacteria, are called propilins or prepilins.

usher Oligomeric outer-membrane proteins that serve as assembly platforms for some types of pili. Usher proteins can also form channels through which nascent pili are extruded from bacteria.

Pili, also known as fimbriae, are proteinaceous, filamentous polymeric organelles expressed on the surface of bacteria. They range from a few fractions of a micrometer to greater than 20 μm in length and vary from less than 2 to 11 nm in diameter. Pili are composed of single or multiple types of protein subunits, called pilins or fimbrins, which are typically arranged in a helical fashion.

Pilus architecture varies from thin, twisting thread-like fibers to thick, rigid rods with small axial holes.

Thin pili with diameters of 2–3 nm, such as K88 and K99 pili, are often referred to as “fibrillae”. Even thinner fibers (<2 nm), which tend to coil up into a fuzzy adhesive mass on the bacterial surface, are referred to as thin aggregative pili or curli. High-resolution electron microscopy of P, type 1, and S pili of *Escherichia coli* and *Haemophilus influenzae* pili has revealed that these structures are composite fibers, consisting of a thick pilus rod attached to a thin, short distally located tip fibrillum. Pili are often expressed peritrichously around individual bacteria, but some, such as type 4 pili, can be localized to one pole of the bacterium.

Pili expressed by gram-negative bacteria have been extensively characterized, and the expression of pili by gram-positive bacteria has also been reported. The numerous types of pili assembled by both gram-negative and gram-positive organisms have been ascribed diverse functions in the adaptation, survival, and spread of both pathogenic and commensal bacteria. Pili can act as receptors for bacteriophage, facilitate DNA uptake and transfer (conjugation), and, in at least type 4 pilus, function in cellular motility. The primary function of most pili, however, is to act as scaffolding for the presentation of specific adhesive moieties. Adhesive pilus subunits (adhesins) are often incorporated as minor components into the tips of pili, but major structural subunits can also function as adhesins. Adhesins can mediate the interaction of bacteria with each other, with inanimate surfaces, and with tissues and cells in susceptible host organisms. The colonization of host tissues by bacterial pathogens typically depends on a stereochemical fit between an adhesin and complementary receptor architecture. Interactions

mediated by adhesive pili can facilitate the formation of bacterial communities such as biofilms and are often critical to the successful colonization of host organisms by both commensal and pathogenic bacteria.

I. HISTORICAL PERSPECTIVE AND CLASSIFICATION OF PILI

Pili were first noted in early electron microscopic investigations as nonflagellar, filamentous appendages of bacteria. In 1955, Duguid designated these appendages "fimbriae" (plural, from Latin for thread or fiber) and correlated their presence with the ability of *E. coli* to agglutinate red blood cells. Ten years later Brinton introduced the term "pilus" (singular, from Latin for hair) to describe the fibrous structures (the F pilus) associated with the conjugative transfer of genetic material between bacteria. Since then "pilus" has become a generic term used to describe all types of nonflagellar filamentous appendages, and it is used interchangeably with the term "fimbria."

Historically, pili have been named and grouped based on phenotypic traits such as adhesive and antigenic properties, distribution among bacterial strains, and microscopic characterizations. In the pioneering work of Duguid and co-workers, pili expressed by different *E. coli* strains were distinguished on the basis of their ability to bind to and agglutinate red blood cells (hemagglutination) in a mannose sensitive (MS) as opposed to a mannose resistant (MR) fashion. Pili mediating MS hemagglutination by *E. coli* were designated

type 1 pili and these pili have since been shown to recognize mannose-containing glycoprotein receptors on host eukaryotic cells. Morphologically and functionally homologous type 1 pili are expressed by many different species of Enterobacteriaceae. Despite their similarities, however, type 1 pili expressed by the various members of the Enterobacteriaceae family are often antigenically and genetically divergent within their major structural subunits. In contrast to type 1 pili, most other pili so far identified are either nonhemagglutinating or mediate MR hemagglutination. These pili are very diverse and possess a myriad of architectures and different receptor binding specificities and functions.

Since the discovery and initial characterization of pili in the 1950s, substantial advances have been made in our understanding of the genetics, biochemistry, and structural and functional aspects of these organelles. A vast number of distinct pilus structures have been described and new types of pili continue to be identified. Pili are now known to be encoded by virtually all gram-negative organisms and are some of the best-characterized colonization and virulence factors in bacteria. Here we classify pili that are expressed by gram-negative bacteria into six groups according to the mechanisms by which they are assembled. This classification scheme is not all inclusive, but provides a convenient means for discussing the diverse types of pili, their functions, structures and assembly. Representatives of various pilus types assembled by the various pathways discussed in the following sections are listed in Table 38.1 and electron micrographs of the various pilus types are shown in Fig. 38.1.

TABLE 38.1 Pilus assembly pathways

Assembly pathway	Structure	Assembly gene products ^a	Organism	Disease(s) associated with pilus expression
Chaperone-Usher pathway				
Thick rigid pili	P pili	PapD/PapC	<i>E. coli</i>	Pyelonephritis/cystitis
	Prs pili	PrsD/PrsC	<i>E. coli</i>	Cystitis
	Type 1 pili	FimC/FimD	<i>E. coli</i> <i>Salmonella</i> sp. <i>K. pneumoniae</i>	Cystitis
	S pili	SfaE/SfaF	<i>E. coli</i>	UTI Newborn meningitis
	F1C pili	FocC/FocD	<i>E. coli</i>	Cystitis

II. CHAPERONE-USHER PATHWAY

All pilins destined for assembly on the surface of gram-negative bacteria must be translocated across the inner membrane, through the periplasm, and across the outer membrane. To accomplish this, various adhesive

organelles in many different bacteria require two specialized assembly proteins, a periplasmic chaperone and an outer membrane usher. Chaperone-usher assembly pathways are involved in the biogenesis of over 30 distinct structures, including composite pili, thin fibrillae, and nonfimbrial adhesins. Here, we focus on the structure and assembly mechanisms of

the prototypical P and type 1 pilus chaperone–usher systems.

A. Molecular architecture

P and type 1 pili are both composite structures consisting of a thin fibrillar tip joined end to end to a right-handed helical rod (Fig. 38.2A and B). Chromosomally located gene clusters that are organizationally and functionally homologous encode P and type 1 pili (Fig. 38.2D and E). The P pilus tip is a 2-nm-wide structure composed of a distally located adhesin (PapG), a tip pilin (PapE), and adaptor pilins (PapF and PapK). The PapG adhesin binds to Gal α (1-4)Gal moieties present in the globoseries of glycolipids found on the surface of erythrocytes and kidney cells. Consistent with this binding specificity, P pili are major virulence factors associated with pyelonephritis caused by uropathogenic *E. coli*. The minor pilin PapF is thought to join the PapG adhesin to the tip fibrillum, the bulk of which is made up of a polymer of PapE subunits. PapK is thought to terminate the growth of the PapE polymer and to join the tip structure to the rod. The pilus rod is composed of multiple PapA subunits joined end to end and then coiled into a right-handed 6.8-nm-thick helical rod having a pitch distance of 24.9 Å and 3.28 subunits per turn. The rod is terminated by a minor subunit, PapH, which may serve to anchor the pilus in the membrane.

Similar to the P pilus structure, the type 1 pilus has a short, 3-nm-wide fibrillar tip made up of the mannose-binding adhesin, FimH, and two additional pilins, FimG and FimF. The FimH adhesin mediates attachment to mannosylated receptors expressed on a wide variety of cell types and has been shown to be a significant virulence determinant for the development of cystitis. The type 1 tip fibrillum is joined to a rod composed predominantly of FimA subunits arranged in a 6- to 7-nm diameter helix with a pitch distance of 23.1 Å and 3.125 subunits per turn. Both type 1 and P pilus rods have central axial holes with diameters of 2–2.5 and 1.5 Å, respectively. Despite the architectural similarities, type 1 pili appear to be more rigid and prone to breaking than P pili. Some reports have argued that, unlike the P pilus system in which the tip subunits are thought to be located only within the tip, some of the type 1 tip subunits may also be occasionally intercalated within the rod structure.

In both P and type 1 pili, the major pilin subunits making up the rods are organized in a head-to-tail manner. Additional quaternary interactions between subunits in adjacent turns of the helical rod appear to stabilize the structure and may help drive the outward growth of the organelle during pilus assembly (see later). The disruption of these latter interactions by mechanical stress or by incubation in 50% glycerol can cause the pilus rod to reversibly unwind into a 2-nm-thick linear fiber similar in appearance to the tip fibrillum (Fig. 38.2C). Bullitt and Makowski (1995) have proposed that the ability of the pilus rods to unwind allows them to support tension over a broader range of lengths. This may help P and type 1 pili better withstand stress, such as shearing forces from the bulk flow of fluid through the urinary tract, without breaking.

In addition to composite structures exemplified by P and type 1 pili, chaperone–usher pathways also mediate the assembly of thin fibrillae such as K88 and K99 pili and nonfimbrial adhesins. K88 and K99 pili are 2- to 4-nm-thick fibers that mediate adherence to receptors on intestinal cells. They are significant virulence factors expressed by enterotoxigenic *E. coli* (ETEC) strains that cause diarrheal diseases in livestock. These pili were given the “K” designation after being mistakenly identified as K antigens in *E. coli*. In contrast to P and type 1 pili, the adhesive properties of K88 and K99 pili are associated with the major pilus subunits. The receptor-binding epitopes on the individual major pilus subunits are exposed on the pilus surface and available for multiple interactions with host tissue. In general, pili with adhesive major subunits, such as K88 and K99 pili, are thin flexible fibrillar structures. In comparison, pili with specialized

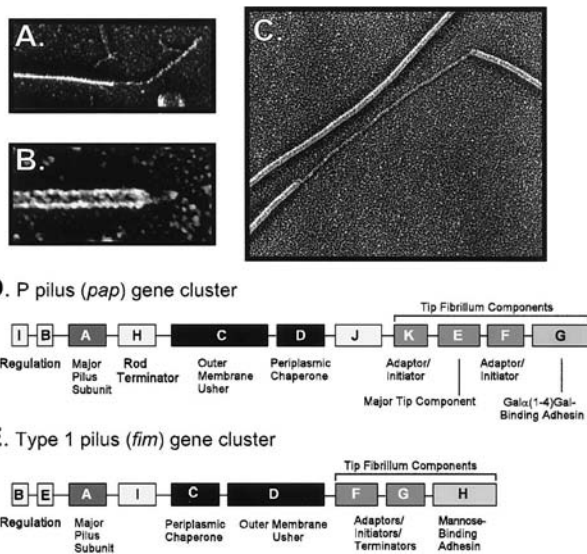

FIGURE 38.2 High-resolution electron micrographs showing the pilus rod and tip fibrillum structures of (A) P and (B) type 1 pili. Unraveling of a portion of a P pilus rod into a linear fiber is shown in (C). The images shown in (A), (B), and (C) are at different magnifications. The P (*pap*) and type 1 (*fim*) gene clusters are depicted in (D) and (E), respectively. These gene clusters share organizational as well as functional homologies.

adhesive tip structures, such as P and type 1 pili, are relatively rigid and rod-like.

B. Assembly model

The assembly of P pili by the chaperone–usher pathway is the best understood of any pilus assembly pathway. PapD is the periplasmic chaperone and PapC is the outer-membrane usher for the P pilus system. These proteins are prototypical representatives of the periplasmic chaperone and outer-membrane usher protein families. Figure 38.3 presents the current model for pilus assembly by the chaperone–usher pathway, as depicted for P pili.

1. Periplasmic chaperones

The PapD chaperone, the PapC usher, and all of the P pilus structural subunits have typical signal

sequences recognized by the *sec* (general secretion) system. The signal sequences are short, mostly hydrophobic amino-terminal motifs that tag proteins for transport across the inner membrane by the *sec* system. This system includes several inner-membrane proteins (SecD to SecF, SecY), a cytoplasmic chaperone (SecB) that binds to presecretory target proteins, a cytoplasmic membrane-associated ATP-Pase (SecE) that provides energy for transport, and a periplasmic signal peptidase. As the P pilus structural subunits emerge from the *sec* translocation machinery into the periplasm, PapD binds to each subunit, facilitating its release from the inner membrane. Each subunit forms an assembly competent, one-to-one complex with PapD. Proper folding of the subunits requires PapD and involves the action of the periplasmic disulfide bond isomerase DsbA. In the absence of PapD, subunits misfold, aggregate, and are subsequently degraded by the periplasmic protease DegP. The misfolding of

FIGURE 38.3 Model of P pilus assembly by the chaperone–usher pathway. Structural subunits for the pilus tip (PapG, PapF, PapE, and PapK) and for the pilus rod (PapA) are translocated across the inner membrane of *E. coli* via the *sec* system. On the periplasmic side of the inner membrane they interact with the chaperone PapD, which facilitates the folding and release of the subunits from the inner membrane. DsbA is required for the proper folding of both the subunits and the PapD chaperone. In the absence of the chaperone, the subunits aggregate and are degraded by the periplasmic protease DegP. The buildup of unchaperoned subunits results in the activation of the Cpx system, increasing the production of periplasmic protein-folding and -degradation proteins. Subunit–chaperone complexes are targeted to the outer membrane usher, PapC, where the chaperone is released and subunit–subunit interactions occur. The PapC usher forms a 2-nm-wide pore through which the assembled pilus structure is extruded as a linear fiber across the outer membrane. Once on the exterior of the cell, the linear PapA polymer forms a thick right-handed helical rod that is unable to slip back through the usher pore. The formation of the coiled PapA rod is thought to help drive the outward growth of the pilus.

P pilus subunits is sensed by the CpxA–CpxR two-component system in which CpxA is an inner membrane-bound sensor or kinase and CpxR is a DNA-binding response regulator (Jones, 1997). Activation of the Cpx system alters the expression of a variety of genes and may help regulate pilus biogenesis.

The three-dimensional crystal structures of both the PapD and FimC chaperones have been solved. Both chaperones consist of two Ig (immunoglobulin)-like domains oriented into a boomerang shape such that a subunit-binding cleft is created between the two domains. A conserved internal salt bridge is thought to maintain the two domains of the chaperone in the appropriate orientation. Using genetics, biochemistry, and crystallography, PapD was found to interact with pilus subunits, in part, by binding to a highly conserved motif present at the carboxyl terminus of all subunits assembled by PapD-like chaperones. The finer details of how PapD-like chaperones interact with pilus subunits were unveiled by the recent determination of the crystal structures of the PapD–PapK and the FimC–FimH chaperone–subunit complexes (Sauer, 1999, and Choudhury, 1999) (Fig. 38.4). This work demonstrated that the PapD and FimC chaperones

both make similar interactions with their respective subunits. Only the PapD–PapK structure is considered here. PapK has a single domain comprised of an Ig fold that lacks the seventh (carboxy-terminal) β -strand that is present in canonical Ig folds. The absence of this strand produces a deep groove along the surface of the pilin subunit and exposes its hydrophobic core. The carboxy-terminal F strand and the A2 strand of PapK form the groove. The PapD chaperone contributes its G_1 β -strand to complete the Ig fold of the PapK subunit by occupying the groove, an interaction termed donor strand complementation. This interaction shields the hydrophobic core of PapK and stabilizes immature pilus subunits within the periplasm. Similar interactions are thought to have a central role in the maturation of subunits assembled by a variety of different chaperone–usher pathways. The residues that make up the carboxy-terminal groove formed by subunits and bound by PapD-like chaperones have been shown by mutagenesis studies to be involved in subunit–subunit interactions within the final pilus structure. Thus, in addition to stabilizing immature pilus subunits, the donor strand complementation interaction also caps one of the interactive surfaces of the

FIGURE 38.4 Ribbon model based on the crystal structure of the PapD periplasmic chaperone complexed with the PapK pilus subunit. PapD is black and the single domain of PapK is gray. The G_1 β -strand in domain 1 of PapD completes the Ig fold of the pilin, occupying the groove formed between the A2 and F strands of PapK. This interaction has been termed donor strand complementation. The eight amino-terminal amino acids of PapK are disordered in the structure. These residues have been implicated in mediating subunit–subunit interactions within the mature pilus organelle. During pilus biogenesis, it is proposed that the amino-terminal strand of a pilin can displace the G_1 β -strand of the chaperone and insert into the carboxy-terminal groove of the neighboring subunit. The mature pilus would thus consist of a linear array of canonical Ig domains, each of whose fold is completed by a strand from the neighboring subunit.

subunit and prevents premature oligomerization and aggregation of pilus subunits within the periplasm.

2. Outer-membrane ushers

After being formed in the periplasm, chaperone-subunit complexes are targeted to the outer-membrane usher where the chaperone is released, exposing interactive surfaces on the subunits that facilitate their assembly into the pilus. Studies in the P and type 1 pilus systems have demonstrated that the adhesin-chaperone complexes, PapDG or FimCH, bind tightest and fastest to the usher and that the adhesins are the first subunits assembled into the pilus. The binding of the chaperone-adhesin complex induces a conformational change in the usher, possibly priming it for pilus assembly. Additional subunits are incorporated into the pilus depending, in part, on the kinetics with which they are partitioned to the usher in complex with the chaperone. Conserved amino-terminal regions, in addition to the conserved carboxy-terminal motif of the pilus subunits, mediate subunit-subunit interactions within the mature pilus. Differences in the complementary surfaces in these conserved regions from one subunit to another may help dictate which of the subunits can be joined to one another during pilus assembly. Thus, the order of the subunits within the final pilus structure is determined by the specific contacts made between the various pilus subunits and also by the differential affinities of the various chaperone-subunit complexes for the usher.

In addition to acting as an assembly platform for the growing pilus, the usher protein appears to have additional roles in pilus biogenesis. High-resolution electron microscopy revealed that the PapC usher is assembled into a 15-nm diameter ring-shaped complex with a 2-nm wide central pore (Thanassi, 1998). PapC and other usher family members are thought to have a predominantly β -sheet secondary structure, typical of outer-membrane pore-forming proteins, and they are predicted to present large regions to the periplasm for interaction with chaperone-subunit complexes. After dissociating from the chaperone at the usher, subunits are incorporated into a growing pilus structure that is predicted to be extruded as a 1-subunit-thick linear fiber through the central pore of the usher complex. The packaging of the linear pilus fiber into a thicker helical rod on the outside surface of the bacterium may provide a driving force for the translocation of the pilus across the outer membrane, possibly acting as a sort of ratcheting mechanism to force the pilus to grow outward. Combined with the targeting affinities of the chaperone-subunit complexes for the usher and the binding specificities of

the subunits for each other, this may provide all the energy and specificity needed for the ordered assembly and translocation of pili across the outer membrane.

III. ALTERNATE CHAPERONE PATHWAY

A variation of the chaperone-usher pilus assembly pathway has been identified in strains of ETEC. These bacteria are major pathogens associated with diarrheal diseases of travelers, infants, and young children. ETEC strains produce several types of uniquely assembled adhesive pili that are considered to be important mediators of bacterial colonization of the intestine. The best studied of these pili is CS1, which appears to be composed predominantly of a major subunit, CooA, with a distally located minor component, CooD. Several CS1-like pili have been identified and include CS2, CS4, CS14, CS17, CS19, and CFA/I pili expressed by various ETEC strains and the cable type II pili of *Burkholderia cepacia*, an opportunistic pathogen of cystic fibrosis patients. Four linked genes, *CooA*, *CooB*, *CooC*, and *CooD*, are the only specific genes required for the synthesis of functional CS1 pili. Homologous genes required for the production of CS2 and CFA/I pili have also been cloned and sequenced. Electron-microscopic examination reveals that the CS1-like pili are architecturally similar to P and type 1 pili assembled by the chaperone-usher pathway (Fig. 38.1B), although none of the proteins involved in the biogenesis of CS1-like pili have any significant sequence homologies to those of any other pilus system.

The assembly of CS1-like pili depends on a specialized set of periplasmic chaperones that are distinct from those of the chaperone-usher pathway described previously. Therefore, we refer to this mode of pilus assembly as the alternate chaperone pathway. In the case of CS1 pili, the chaperone CooB binds to and stabilizes the major and minor pilin subunits, CooA and CooD, which enter into the periplasm in a *sec*-dependent fashion (Fig. 38.5). Both CooA and CooD share a conserved sequence motif near their carboxy-termini that may function as a chaperone-recognition motif. One of the functions of CooB appears to be the delivery of the pilin subunits to an outer-membrane protein, CooC, which may function as a channel, or usher, for the assembly of pilus fibers. In addition to the pilin subunits, CooB also binds to and stabilizes CooC in the outer membrane. In the absence of the CooB chaperone, CooC and the pilin subunits are degraded. Although less well defined, the assembly of CS1 and related structures appears

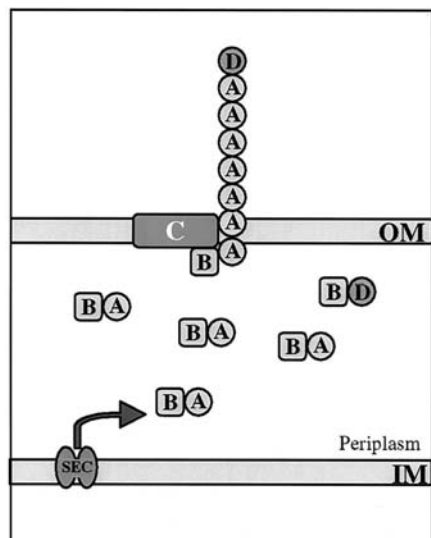

FIGURE 38.5 Assembly of CS1 pili from *E. coli* via the alternate chaperone pathway. The CooB chaperone forms periplasmic complexes with the main components of the pilus, CooA and CooD. It also appears to bind and stabilize the outer-membrane protein CooC in the absence of subunits. CooC appears to function as an outer-membrane (OM) channel for passage of the pilin fiber IM indicates innermembrane.

similar in many respects to the assembly of pili by the classic chaperone–usher pathway. Because CS1-like pili do not appear to be related to those assembled by the chaperone–usher pathway, it has been suggested that these two pilus assembly systems arose independently through convergent evolution.

IV. TYPE II SECRETION PATHWAY FOR TYPE 4 PILUS ASSEMBLY

Type 4 pili are multifunctional structures expressed by a wide diversity of bacterial pathogens. These include *Pseudomonas aeruginosa*, *Neisseria gonorrhoeae* and *N. meningitidis*, *Moraxella* species, *Azoarcus* species, *Dichelobacter nodus*, and many other species classified in these and other genera. Type 4 pili are significant colonization factors and have been shown to mediate bacterial interactions with animal, plant, and fungal cells. In addition, these pili can modulate target-cell specificity, function in DNA uptake and biofilm formation, and act as receptors for bacteriophage. Type 4 pili are also associated with a flagella-independent form of bacterial locomotion, called twitching motility, which allows for the lateral spread of bacteria across a surface.

Type 4 pili are 6-nm-wide structures typically assembled at one pole of the bacterium. They can extend up to several micrometers in length and are

made up of, primarily if not completely, a small subunit usually in the range of 145–160 amino acids. These subunits have distinctive features, including a short (6–7 amino acids), positively charged leader sequence that is cleaved during assembly, *N*-methylphenylalanine as the first residue of the mature subunit, and a highly conserved, hydrophobic amino-terminal domain. The adhesive properties of type 4 pili are, in general, determined by the major pilus subunit. Additional minor components, however, may associate with these pili and alter their binding specificities. In the case of *Neisseria*, a tip-localized adhesin, PilC1, appears to mediate bacterial adherence to epithelial cells.

Recently, a second class of type 4 pili, referred to as class B or type 4B, has been defined. Type 4B pili were initially characterized in enteric pathogens and include the toxin-coregulated pilus (TCP) of *Vibrio cholera*, the bundle-forming pilus (BFP) of enteropathogenic *E. coli* (EPEC), and the longus and CFA/III pili of ETEC. Compared to the typical type 4 pilins (referred to as class A or type 4A), the known type 4B pilins are somewhat larger and have a longer (13–30 amino acids) leader sequence. Also, in place of *N*-methyl-phenylalanine as the first amino acid in the mature pilus subunit, type 4B subunits have other methylated residues such as *N*-methyl-methionine for TCP and *N*-methyl-leucine for BFP. TCP, BFP, and longus pili form large polar bundles over 15 μm in length (Fig. 38.1C). In contrast, CFA/III pili are 1–10 μm long and are peritrichously expressed. The number of pili classified as type 4B is increasing and now includes the R64 thin pilus, an organelle involved in bacterial conjugation.

Parge and coworkers solved the crystal structure of the type 4A pilin subunit (PilE) from *N. gonorrhoeae* in 1995. This work greatly advanced understanding of the structure, function, and biogenesis of type 4 pili. PilE contains 158 amino acids and was determined to have an overall ladle shape, being made up of an α - β roll with a long hydrophobic amino-terminal α -helical spine (residues 2–54) (Fig. 38.6). All type 4 pilins (types 4A and 4B) are predicted to have a fairly similar structure. The carboxy-terminal domain of type 4 pilins possesses hypervariable regions that affect the binding specificities and antigenicity of type 4 pili. In PilE, these hypervariable regions include a sugar loop (residues 55–77) with an O-linked disaccharide at position Ser-63 and a disulfide-containing region (residues 121–158), which, despite having a hypervariable nature, adopts a regular β -hairpin structure (β_5 - β_6) followed by an extended carboxy-terminal tail. A disulfide-containing carboxy-terminal hypervariable region is common among the type 4 pilins. The remainder of PilE was

FIGURE 38.6 Ribbon model of the type 4A pilin PilE from *N. gonorrhoeae*. Secondary structural elements include a hydrophobic, conserved amino-terminal α -helical spine connected to a variable domain containing an extended sugar loop with an O-linked disaccharide at position Ser-63 and a disulfide-containing carboxy-terminal region. The disulfide bridge is indicated by a dotted line.

shown to consist of two β -hairpins forming a four-stranded antiparallel β -sheet (residues 78–93 and 103–122) with a connecting β_2 – β_3 loop region (residues 94–102).

Through systematic modeling, Parge *et al.* showed that PilE was probably assembled into pili as monomers arranged in a helix with about five PilE subunits per turn and a pitch distance of approximately 41 Å. PilE subunits are predicted to be packed into pili as a three-layer assemblage consisting of an inner core of coiled conserved hydrophobic α -helices surrounded by β -sheets and an outermost layer composed of the disaccharide and hypervariable regions. Hydrophobic packing of the inner core of α -helices along with the flexibility of these helices may permit type 4 pili to bend and adopt twisted, bundled conformations, as seen in Fig. 38.1C. Hydrogen bonds throughout the middle layer of β -sheets may provide much of the mechanical stability for the pilus. The hypervariable outermost layer is not an integral part of the pilus structure and associates with the middle layer of β -sheets through only a few conserved interactions.

Thus, the outermost region can be structurally pliant and accommodate extreme amino acid changes that can lead to antigenic variation and altered binding specificities without disrupting the assembly of the pilus. The antigenic characteristics of type 4 pili synthesized by *N. gonorrhoeae* can be modified extensively by a remarkable mechanism. This pathogen encodes more than 15 distinct silent pilin genes, termed PilS, that lack the invariant amino-terminal domain present in PilE. By recombination of silent PilS genes with the PilE locus, a single neisserial strain can theoretically express greater than 10 million PilE variants.

The biogenesis of type 4 pili is substantially more complicated than pilus assembly by the chaperone-usher or alternate chaperone pathways. Type 4 pilus assembly requires the expression of a myriad of genes that are usually located in various unlinked regions on the chromosome. Exceptions include TCP, BFP, and the R64 thin pilus, which are currently the only type 4 pili for which the majority of the genes required for pilus biogenesis are located within a single genetic locus. Although chromosomally located genes encode most type 4A pili, all known type 4B pili, with the exception of TCP, are encoded by plasmids. The number of genes essential for type 4 pilus biogenesis and function ranges from 14 (for pili such as BFP) to over 20 (for structures such as the type 4A pili of *N. gonorrhoeae*). In *P. aeruginosa*, it is estimated that about 0.5% of the bacterium's genome is involved in the synthesis and function of type 4 pili. Among the various bacterial species expressing type 4 pili, the genes encoding the type 4 pilus structural components are similar, whereas the regulatory components surrounding them are typically less conserved.

Several gene products are currently known to be central to the assembly of type 4 pili. These include a prepilin peptidase that cleaves off the leader peptide from nascent pilin subunits; a polytopic inner membrane protein that may act as a platform for pilus assembly; a hydrophilic nucleotide-binding protein located in the cytoplasm or associated with the cytoplasmic face of the inner membrane, which may provide energy for pilus assembly; and an outer-membrane protein complex that forms a pore for passage of the pilus to the exterior of the bacterium. Many of the components involved in type 4 pilus assembly share homology with proteins that are part of DNA uptake and protein secretion systems, collectively known as the main terminal branch of the general secretory (*sec*-dependent) pathway, or type II secretion. These secretion pathways encode proteins with type 4 pilin-like characteristics and other proteins with homology to type 4 prepilin peptidases and

outer-membrane pore-forming proteins. Whether type II secretion systems can assemble pili or piluslike structures is not known.

Meyer and colleagues have described a model for type 4 pilus assembly in *N. gonorrhoea* (Fig. 38.7). The PilE prepilin subunits are transported into the periplasm by the *sec* translocation machinery. Following translocation, the prepilin subunits remain anchored in the inner membrane by their hydrophobic amino-terminal α -helical domains, with their hydrophilic carboxy-terminal heads oriented toward the periplasm. The removal of the positively charged PilE prepilin leader sequence by the PilD signal peptidase drives the hydrophobic stems of the PilE subunits to associate to form a pilus. An inner-membrane assembly complex made up of several proteins including PilD, PilF, PilG, and PilT aids this process. The assembled pilus penetrates the outer membrane through a gated pore formed by the multimeric complex Omc. The PilC adhesin associated with the tips of type 4 pili produced by *N. gonorrhoea* may facilitate passage of the nascent pili through the Omc pore. One implication of this assembly model is that the amino-terminal region of PilE resides in a continuous hydrophobic environment during both inner-membrane

transport and pilus assembly. This may allow polymerization and, interestingly, depolymerization of the pilus to proceed with only minimal energy requirements. Continued extension and retraction of type 4 pili by rounds of polymerization and depolymerization reactions are proposed as the basis of twitching motility, one of the functions of type 4 pili. This process could be controlled by nucleotide-binding proteins such as PilT, PilB, and PilU associated with the inner-membrane assembly complex. The capacity of type 4 pili to depolymerize may also provide a means for transforming DNA, which could potentially interact with the type 4 pilus fiber, to enter into the bacterial cell.

V. CONJUGATIVE PILUS ASSEMBLY PATHWAY

In gram-negative bacteria, certain pili, collectively known as conjugative pili, facilitate the interbacterial transfer of DNA. These pili allow donor and recipient bacteria to make specific and stable intercellular contacts before DNA transfer is initiated. In some cases, conjugative pili may also form the conduits for intercellular DNA transfer. Horizontal gene transfer, or conjugation, mediated by conjugative pili is inextricably associated with the spread of antibiotic resistance among bacterial pathogens. Conjugative pili are generally encoded by self-transmissible plasmids that are capable of passing a copy of their genes to a recipient bacterium. Closely related plasmids, with similar replication control systems, are unable to coexist in the same cell. This property has been termed incompatibility, and provides the primary basis for cataloging conjugal plasmids and the pili that they encode. Thus far, in *E. coli* alone, over 25 incompatibility groups made up of well over 100 distinct plasmids have been defined. Plasmids of a particular incompatibility group usually encode conjugative pili with similar antigenic properties, sensitivities to pilus-specific phages, and morphologies.

Among the multitude of known incompatibility groups, three morphologically and functionally distinct types of conjugative pili have been defined: rigid, thick flexible, and thin flexible pili. Rigid conjugative pili are 8- to 11-nm-wide structures that are usually specified by conjugal DNA transfer systems that function well only on solid surfaces. Thick flexible pili, on the other hand, are 8- to 11-nm-wide structures that typically, but not always, promote conjugation on solid surfaces and in liquid media equally well. Conjugal DNA transfer promoted by rigid or thick flexible pili can be enhanced, in some cases, by

FIGURE 38.7 Model of type 4 pilus assembly by *N. gonorrhoeae*. The PilE prepilin is translocated into the periplasm aided by the *sec* machinery. PilE is processed by the PilD signal peptidase, which cleaves the positively charged leader sequence from the amino-terminus of the prepilin subunit. An inner-membrane assembly complex then assembles the mature PilE subunit into a pilus fiber. PilQ mediates translocation of the pilus through the outer membrane, possibly with the assistance of other factors, such as PilP. The PilC adhesin, which appears to be incorporated at the tip of the growing pilus fiber, also seems to be required for translocation of the pilus through the outer membrane.

the presence of thin flexible pili. These pili are similar in appearance to type 4 pili and at least one member of the thin flexible pilus group (the R64 thin pilus) has been identified at the molecular level as a type 4B pilus (described previously). Thin flexible pili appear to function primarily in the stabilization of bacterial mating pairs, increasing the rate of DNA transfer. Conjugation does not occur in the presence of thin flexible pili alone, or in the absence of rigid or thick flexible pili.

The most thoroughly studied conjugative pilus is the F pilus encoded by the self-transmissible, broad host range F (fertility) plasmid, a member of the F1 incompatibility (IncF1) group of plasmids borne by *E. coli*. The F pilus system is prototypical for numerous other conjugation systems and F-pilus biogenesis is distinct from type 4 and other pilus assembly pathways. F pili are 8-nm-thick, flexible helical filaments composed primarily, if not completely, of repeating 7.2-kDa (70-amino-acid) TraA pilin subunits. Donor (F⁺) cells typically express one to three F pili that are usually 1–2 μ m long. Each F pilus possesses a 2-nm-wide central channel that is lined by basic hydrophilic residues, which could potentially interact with negatively charged DNA or RNA molecules during conjugation. TraA is organized into pentameric, doughnut-like disks that are stacked in the pilus such that successive disks are translated 1.28 nm along the pilus axis and rotated 28.8° with respect to the lower disk. The TraA pilin has two hydrophobic domains located toward the center and at the carboxy-terminus of the pilin. The hydrophobic domains are thought to extend as antiparallel α -helices from the central axis to the periphery of the pilus shaft. These domains are separated by a short basic region that appears to form the hydrophilic wall of the central channel of the pilus. The amino-terminal domain of TraA is predicted to face the exterior of the pilus. However, this domain is antigenically masked when the amino-terminal residue of TraA is acetylated during maturation of the pilin (see later). This modification is common among all known F-like pilins and appears to cause the amino-terminal domain to be tucked back into or along the pilus shaft. Acetylation is not essential for F-pilus assembly or function, but does help prevent aggregation of F-like pili and affects the phage-binding characteristics of these organelles. Phage are also known to recognize the carboxy-terminal hydrophobic domain of TraA. Although masked within the pilus shaft, the acetylated amino-terminal domain of TraA appears to be exposed in unassembled pilin subunits and at the distal tips of pili. The F pilus tip is believed to initiate contact between donor and recipient cells during conjugation. Alterations in the amino-terminal

sequence of TraA provide the primary basis for the antigenic diversity observed among various F-like pili.

At least 16 gene products encoded by the F plasmid are involved in F pilus assembly and an additional 20 or more are needed for conjugation. Two gene products, TraQ and TraX, mediate the processing of the TraA pilin to its mature form. TraA is synthesized as a 12.8-kDa (121-amino-acid) cytoplasmic propilin that is translocated across the inner membrane where it is proteolytically processed by host signal peptidase I to yield the 7.2-kDa pilin form. TraQ, an innermembrane protein, facilitates the translocation process and may help position the TraA propilin for processing into mature pilin. In the absence of TraQ, the translocation of TraA is disrupted and most of the pilin is degraded. After processing, the amino-terminal residue (alanine) of TraA is acetylated by TraX, a polytopic innermembrane protein. Whereas TraQ and TraX are involved in the maturation of the TraA pilin, 13 additional gene products (TraL, TraB, TraE, TraK, TraV, TraC, TraW, TraU, TraF, TraH, TraG, TrbC, and TrbI) affect the assembly of TraA into the pilus filament. Most of these proteins appear to associate with either the inner or outer bacterial membrane and may constitute a pilus assembly complex that spans the periplasmic space.

The exact mechanism by which TraA is assembled into pili is not defined. The mature TraA pilin accumulates in the inner membrane with its amino-terminus facing the periplasm. Both hydrophobic domains of TraA span the inner membrane, with the hydrophilic region of TraA connecting them on the cytoplasmic side. Small clusters of TraA also accumulate in the outer membrane and these may function as intermediates in F pilus assembly and disassembly. Large portions of the TraA sequence have the propensity to assume both β -sheet and α -helical structures, although the α -helical conformation is known to predominate in assembled pili. Frost and co-workers (1984, 1993) have suggested that a shift between β -sheet and α -helical conformations may drive pilus assembly and disassembly. F pilus assembly is energy dependent and the depletion of ATP levels by respiratory poisons such as cyanide results in F pilus depolymerization and retraction. It has been postulated that TraA is normally cycled between pili and periplasmic and inner-membrane pools by rounds of pilus outgrowth and subsequent retraction. During conjugation, F pilus retraction is thought to serve a stabilizing function by shortening the distance between bacterial mating pairs and allowing for more intimate contact.

Several components of the F pilus assembly machinery share significant homology with proteins encoded by other conjugative systems. These include

proteins specified by broad host range plasmids in other incompatibility groups (such as IncN, IncP, and IncW) and many of the proteins encoded by the Ti plasmid-specific *vir* genes of the plant pathogen *Agrobacterium tumefaciens*. These bacteria elaborate 10-nm-wide promiscuous conjugative pili, called T pili (Fig. 38.1D), which direct the interkingdom transfer of a specific genetic element, known as T-DNA, into plant and yeast cells. The introduction of T-DNA into plant cells induces plant tumor formation. T pilus assembly by *A. tumefaciens* requires the expression of at least 12 *vir* gene products encoded by the Ti plasmid. VirB2 is the major, and possibly only, component of the T pilus and it is predicted to be structurally homologous to the F pilus subunit TraA.

Other than possibly stabilizing donor-recipient interactions, it is not clear how F and T pili or any pilus structures function in conjugative DNA-transfer processes. However, substantial evidence exists, at least in the case of F pili, suggesting that pilus components or the pilus itself can serve as a specialized channel for the transmission of DNA and any accompanying pilot proteins across the donor and possibly the recipient cell membranes. In light of this possibility, it is interesting to note that many components of the conjugative pilus systems encoded by the IncF, IncN, IncP, and IncW plasmids and by the *vir* genes of *A. tumefaciens* are similar to the Ptl proteins responsible for the export of the multiple subunit toxin of *Bordetella pertussis*. Furthermore, these secretion systems seem to be distantly related to transport systems used by *Legionella pneumophila* and *Helicobacter pylori* to inject virulence factors into host eukaryotic cells. Conjugative pilus systems such as those encoding F and T pili thus appear to be representative of a larger family of macromolecular transport systems. These type IV secretion systems (not to be confused with the secretion of autotransporters, such as IgA proteases, which is also known as type IV secretion) represent a major pathway for the transfer of both nucleic acid and proteins between cells (Zupan *et al.*, 1998). The understanding of how conjugative pili help mediate the intercellular transfer of macromolecules remains a significant challenge.

VI. EXTRACELLULAR NUCLEATION-PRECIPIATION PATHWAY

Many strains of *E. coli* and *Salmonella enteritidis* produce a class of thin (<2 nm), irregular, and highly aggregated surface fibers known as curli (Fig. 38.1E). These distinct organelles mediate binding to a variety

of host proteins, including plasminogen, fibronectin, and human contact-phase proteins. They are also involved in bacterial colonization of inert surfaces and have been implicated in biofilm formation. Curli are highly stable structures and extreme chemical treatment is required to depolymerize them. The major component of *E. coli* curli is a 15.3-kDa protein known as CsgA, which shares over 86% primary sequence similarity to its counterpart in *S. enteritidis*, AgfA.

The formation of curli represents a departure from the other modes of pilus assembly. Whereas structures exemplified by P, CS1, type 4, and F pili are assembled from the base, curli formation occurs on the outer surface of the bacterium by the precipitation of secreted soluble pilin subunits into thin fibers (Fig. 38.8). In *E. coli*, the products of two divergently transcribed operons are required for curli assembly. The *csgBA* operon encodes the primary fiber-forming subunit, CsgA, which is secreted as a soluble protein directly into the extracellular environment. The second protein encoded by the *csgBA* operon, CsgB, is proposed as inducing polymerization of CsgA at the cell surface. In support of this model, it has been demonstrated that a CsgA⁺CsgB⁻ donor strain can secrete CsgA subunits that can be assembled into curli on the surface of a CsgA CsgB⁺ recipient strain. Furthermore, CsgB appears to be interspersed along the length of the curli fiber, where it may initiate branching of the curli structures. In the absence of

FIGURE 38.8 Model of curli assembly by the extracellular nucleation-precipitation pathway. CsgA, the main component of curli from *E. coli*, is secreted across the outer membrane. Surface-localized CsgB serves to nucleate CsgA assembly. CsgB is also found distributed along the curli fiber, where it may serve to initiate branching of the fiber. CsgG is an outer membrane-localized lipoprotein that is required for the secretion of CsgA and CsgB, although its function is not clear.

CsgA, overexpressed CsgB is able to form short polymers on the bacterial cell surface.

The *csgDEFG* operon encodes a gene for a transcriptional activator of curli synthesis (CsgD), and three genes encoding putative assembly factors. One of these factors, CsgG, has been shown to be a lipoprotein that is localized to the outer membrane. In the absence of CsgG, curli assembly does not take place and CsgA and CsgB are rapidly degraded. The precise role of CsgG is not known. Normark and colleagues have suggested that CsgG might act as a chaperone that facilitates the secretion of the CsgA and CsgB and protects them from degradation within the periplasm. It is also possible that CsgG assembles into multimers that could function as a Csg-specific channel within the outer membrane. The roles of the *CsgE* and *CsgF* gene products are not known. It has been reported, however, that a strain lacking these two factors can export assembly-competent CsgA, suggesting that the production of CsgG alone is sufficient for functional maturation of the CsgA subunit of curli.

VII. TYPE III SECRETION PATHWAY

The various pilus assembly pathways described in the previous sections all rely on components of the *sec* machinery for the translocation of their respective pilus subunits across the inner membrane. Two new types of pili that are assembled by a *sec*-independent pathway known as type III secretion have been identified. The type III secretion system is encoded by numerous gram-negative pathogens and enables these bacteria to secrete and inject pathogenic effector molecules into the cytosol of host eukaryotic cells. About 20 gene products, most of which are inner-membrane proteins, make up the type III secretion system. The components mediating type III secretion are conserved in pathogens as diverse as *Yersinia* and *Erwinia*, but the secreted effector proteins vary significantly among species. The type III secretion apparatus, which appears to span the periplasmic space, resembles the basal body of a flagellum connected to a straight rod that extends across the outer membrane. Interestingly, all type III secretion systems encode some components with homologies to proteins involved in flagellar assembly. The secretion of proteins by the type III system is an ATP-dependent process that involves no distinct periplasmic intermediates. Type III-secreted proteins of EPEC and the plant pathogen *Pseudomonas syringae* have recently been shown to assemble into piluslike structures.

EPEC encodes four proteins, EspA, EspB, EspD, and Tir, that are secreted by a type III pathway. These

proteins facilitate intimate contact between the pathogen and host intestinal cells and are required for the formation of specific (attaching and effacing) lesions. Knutton and colleagues (1998) showed that one of these proteins, EspA, can assemble into 7- to 8-nm thick peritrichously expressed pilus-like fibers that are organized into ~50-nm-wide bundles that extend up to 2 μ m from the bacterial surface (Fig. 38.1F). These fibers appear to be made up of only EspA molecules. Interestingly, EspA shares substantial sequence identity with a flagellin from *Y. enterocolitica*. During the infection process, the EspA fibers appear to mediate contact between EPEC and the host-cell surface prior to the establishment of more intimate bacterial attachment. The EspA fibers seem to assist the translocation of EspB effector molecules into host cells, where they can subvert host signal-transduction pathways.

In *P. syringae* and other plant pathogens, hypersensitive response and pathogenicity (*hrp*) genes control the ability of these bacteria to cause disease in susceptible plants and to elicit the hypersensitive response in resistant plants. The hypersensitive response is a phenomenon characterized by rapid localized host-cell death at the site of infection that appears to limit the spread of a pathogen in an infected plant. A subset of the *hrp* genes, recently renamed *hrc* genes, encode components of a type III secretion system. In 1997, Roine and co-workers showed that one of the proteins, HrpA, secreted by the Hrp type III secretion system is assembled into 6- to 8-nm-wide, peritrichously expressed pili. It was proposed that these pili, known as Hrp pili, are involved in mediating bacteria-plant interactions in the intercellular spaces of the host plant. In addition, Hrp pili may assist the delivery of effector proteins into host-plant cells. The exact nature and functions of the Hrp pili of *P. syringae* and the EspA-containing pili of EPEC remain to be elucidated.

VIII. REGULATION OF PILUS BIOGENESIS

Pilus biogenesis, in general, is a tightly regulated process. Ideally, the costs in energy and other resources required for pilus assembly must be balanced with any potential benefits that pilus expression might provide a bacterium. For example, by producing pili in a nutritionally poor environment a bacterium will tax its available resources, but with pili the same bacterium may be able to gain access to a more favorable location. Pathogenic and other bacteria must also control pilus expression, in some cases, to avoid attachment to unfavorable sites (tissues)

within their hosts. Furthermore, pathogenic bacteria may need to modulate pilus expression to escape detection by the host immune system. Whether a bacterium expresses pili is greatly affected by environmental factors. Changes in temperature, osmolarity, pH, oxygen tension, carbon source, and nutrient availability may either increase or decrease pilus expression. The presence of iron, aliphatic amino acids, and electron acceptors other than oxygen may also influence the expression of pili. A combination of these environmental cues can stimulate (or repress) pilus synthesis and alter the expression of a variety of other factors, all of which can influence the tropism of bacteria for specific niches in the environment or in host organisms.

Environmental signals affect pilus biogenesis through global regulator proteins that can modify the transcription of pilus genes. Various global regulators have been identified and include H-NS, a DNA-binding histone-like protein that often mediates temperature regulation of pilus synthesis. H-NS appears to alter DNA topology and typically functions as a negative regulator. Regulation by carbon source can occur through the catabolite activator protein (CAP), whereas the leucine-responsive regulatory protein (Lrp) can modulate pilus expression in response to aliphatic amino acids. The CAP and Lrp regulators can control sets of pilus operons, enabling the expression of different types of pili to be coordinated and integrated with the metabolic state of the bacterial cells. In addition to these and other global regulators, specific regulator proteins encoded by genes within some pilus operons may also modulate pilus biogenesis. Multiple regulatory factors can act upon the same promoter region, switching pilus gene expression from on to off and vice versa. This on-and-off switching, known as phase variation, can also be modulated by the methylation status of a promoter region and by the inversion of sequence elements within a promoter. Two-component systems, such as the Cpx system described for P pilus assembly, also appear to be involved, at least tangentially, in the regulation of the assembly and function of a large number of pilus types.

IX. ROLE OF PILI IN DISEASE PROCESSES

The expression of pili can have substantial impact on the establishment and persistence of pathogenic bacteria in their hosts. For many bacterial pathogens, adhesive pili play a key role in the colonization of host tissues. Uropathogenic *E. coli*, for example,

require type 1 pili to effectively colonize the bladder epithelium. These pili attach to conserved, mannose-containing host receptors expressed by the bladder epithelium and help prevent the bacteria from being washed from the body with the flow of urine. P pili may serve a similar function in the kidneys, inhibiting the clearance of pyelonephritic *E. coli* from the upper urinary tract. Enteric pathogens produce a wide variety of adhesive pili that facilitate bacterial colonization of the intestinal tract. These include the K88, K99, and 987P pili made by ETEC strains, the long-polar fimbriae (LPF) and plasmid-encoded fimbriae (PEF) of *S. enterica*, and the aggregative adherence fimbriae (AAF) of enteroaggregative *E. coli*. In the small intestine, TCP are essential for the attachment of *V. cholera* to gut epithelial cells. These pili also act as receptors for the cholera toxin phage (CTX Φ), a lysogenic phage that encodes the two subunits of the cholera toxin. This phage, with its encoded toxin, is transferred between *V. cholera* strains via interactions with TCP in the small intestine. Other pili also function in the acquisition of virulence factors. The uptake of DNA facilitated by type 4 pili and DNA transfer directed by conjugative pili can provide pathogens with accessory genes enabling them to synthesize a wider repertoire of virulence factors and giving them resistance to a greater number of antibiotics. Biofilm formation, which in some cases appears to require pili such as type 1, type 4, or curli, can also increase the resistance of bacteria to antibiotic treatments and may aid bacterial colonization of tissues and medical implants.

Pili are not necessarily static organelles and dynamic alterations of pilus structures during the infection process may influence the pathogenicity of pilated bacteria. For example, electron-microscopic studies (Mulvey, 1998) of mouse bladders infected with type 1-piliated uropathogenic *E. coli* showed that the pili mediating bacterial adherence to the bladder epithelial cells were 10–20 times shorter than typical type 1 pili. It is possible that the shorter type 1 pili observed are the result of pilus retraction, or breakage, during the infection process. The shortening of type 1 pili may provide a means for reeling bacteria in toward their target host cells, allowing the bacteria to make intimate contact with the bladder epithelium after the initial attachment at a distance. Within the gut, type 4B BFP promote the autoaggregation of EPEC strains, a phenomenon that probably facilitates the initial adherence of EPEC to the intestinal epithelium. Work by Bieber and co-workers (1998) suggests that, after initial attachment, an energy-dependent conformational change in the quaternary structure of BFP is needed for the further dispersal of EPEC over

human intestinal cells and for the full virulence of this pathogen.

During the infection process, adhesive pili are often situated at the interface between host and pathogen where they can potentially mediate cross-talk between the two organisms. A few examples of pilus attachment inducing signal-transduction pathways in host eukaryotic cells have been reported. The binding of the type 4A pili of *Neisseria* to host receptors (probably CD46) on target epithelial cells has been shown to stimulate the release of intracellular Ca^{2+} stores, a signal known to control a multitude of eukaryotic cellular responses. Similarly, the attachment of P pili to Gal α (1-4)Gal-containing host receptors on target uroepithelial cells can trigger the intracellular release of ceramides, important second-messenger molecules that are capable of activating a variety of protein kinases and phosphatases involved in signal transduction processes. The signals induced in uroepithelial cells upon the binding of P-piliated bacteria eventually result in the secretion of several immunoregulatory cytokines. The binding of type-1-piliated bacteria to mannosylated receptors on uroepithelial cells can similarly induce the release of cytokines, although apparently through different signaling pathways than those stimulated by P pilus binding. Pili can also transduce signals into bacterial cells. This was demonstrated by Zhang and Normark who, in 1996, showed that the binding of P pili to host receptors stimulated the activation of iron-acquisition machinery in uropathogenic *E. coli*. This probably increases the ability of uropathogens to obtain iron and survive in the iron-poor environment of the urinary tract. An understanding of how pili can transmit signals into bacterial cells, and the consequences of such signaling, awaits future studies. Continued research into the biogenesis, structure, and function of pili promises not only to advance our basic understanding of the role of these organelles in pathogenic processes, but may also aid the development of a new generation of antimicrobial therapeutics and vaccines.

Flagella

Shin-Ichi Aizawa

Japan Science & Technology Agency

GLOSSARY

flagellar basal body The major structure of the flagellar motor, consisting of ring structures and a rod.

flagellar motor A molecular machine that converts the energy of proton flow into rotational force.

master genes Flagellar genes that regulate the expression of all the other flagellar genes, sitting at the top of the hierarchy of flagellar regulons.

polymorphic transition The interconversion of helical forms on a flagellar filament in a discrete or stepwise manner.

type III secretion system One of the protein export systems that does not use the general secretory pathway. It consists of many protein components.

The Flagellum is an organelle of bacterial motility. It consists of several substructures: the filament, the hook, the basal body, the C ring, and the C rod. The flagellar motor, an actively functional part of the flagellum, can generate torque from proton-motive force. The structural aspects of the flagellum are described here, revealed in pursuit of the identity of the flagellar motor.

I. STRUCTURE

A. Filament

The flagellum is a complex structure composed of many different kinds of proteins. However, the term flagellum, especially in earlier studies, often indicates

the flagellar filament only, because the filament is the major portion of the entire flagellum. In this section, I describe the filament and occasionally call the filament just flagellum.

1. Number of flagella per cell

The number and location of flagella on a cell are readily discernible traits for the classification of bacterial species.

The number ranges from one to several hundred, depending on the species; hence the nomenclature, monotrichous (one) or multitrichous (two or more). Occasionally the term “amphitrichous” is used for two flagella.

There are three possible locations on a cell body for flagella to grow—polar (at the axial ends of the cell body), lateral (at the middle of the cell body), or peritrichous (anywhere around the cell body). In some cases, “lateral” is used as the counterpart of “polar,” as in the two-flagellar systems of *Vibrio alginolyticus*, polar sheathed flagellum and lateral plain flagella (although the latter are actually peritrichous). A tuft of flagella growing from a pole is called lophotrichous. In most cases, flagella can be named by a combination of number and location, for example, polar lophotrichous flagella of *Spirillum volutans*.

Although ordinary flagella are exposed to the medium, some flagella are wrapped with a sheath derived from the outer membrane (e.g., in *Vibrio cholerae*). In an extreme case such as spirochetes, flagella are confined in a narrow space between the outer

membrane and the cell cylinder. The flagella still can rotate; the helical cell body works as a screw, and the flagella counterbalance the torque of the cell body.

2. Filament shape

The filament shape is helical. In theory, there are two types of helices, right-handed and left-handed; in reality, *Salmonella* spp. have left-handed filaments and *Caulobacter crescentus* has a right-handed filament. However, it should be noted that the shapes of these two helices are not mirror images of each other.

There are several detailed filament shapes, and it will be convenient to use the names of the typical shapes found in *Salmonella* spp.—normal (left-handed), curly (right-handed), coiled (left-handed), semi-coiled (right-handed), and straight. The helical parameters of these helices are discrete and distinguishable from one another (Fig. 39.1).

Flagella can switch among a set of helical shapes under appropriate conditions; both helical pitch and helical handedness are interchangeable. The transformation of shapes can be induced by physical perturbation (torque, temperature, pH, and salt concentration of medium). Genetic changes such as point mutations in the flagellin (the component protein of the flagellar filament) gene also result in transformation of helices, but some mutant flagella, such as straight flagella, are too stiff to transform into another helix. This phenomenon, called polymorphism of flagella, is a visible example of conformational changes in proteins and therefore has evoked an idea of a functional role of flagella in motility. Could polymorphism of the flagellum by itself cause the motion? The answer is “no.” Flagella are passive in terms of force generation.

FIGURE 39.1. Helical forms of flagellar filaments. Helices are seen from a position slightly off their axial direction so that the handedness can be easily visualized. The figure shows five typical forms with their helical parameters (p , pitch; d , diameter): (a) normal ($p = 2.55 \mu\text{m}$, $d = 0.6 \mu\text{m}$); (b) coiled ($p = 0$, $d = 1.0 \mu\text{m}$); (c) semi-coiled ($p = 1.26 \mu\text{m}$, $d = 0.5 \mu\text{m}$); (d) curly ($p = 1.20 \mu\text{m}$, $d = 0.2 \mu\text{m}$); and (e) straight filament ($p = \infty$, $d = 0$).

Polymorphism of flagella is observed to occur naturally on actively motile cells with peritrichous flagella. The helical transformation is necessary for untangling a jammed bundle of tangled flagella. When normal flagella in a jammed bundle are transformed into curly flagella, knots of tangled flagella run toward the free end of each flagellum to untangle the jammed bundle.

A theoretical model that explains the polymorphism successfully was presented by Dr. Chris Calladine (University of Cambridge). Twisting and bending a cylindrical rod gives rise to a helix. This model predicts 12 shapes, and eight of them have been found in existing filaments: straight with a left-handed twist, fl, normal, coiled, semi-coiled, curly I, curly II, and straight with a right-handed twist. Only a small energy barrier seems to lie between any two neighboring shapes. Polymorphic transition occurs from one shape to its neighbors; for example, in a transition from normal to curly, the filament briefly takes on coiled and semi-coiled forms.

3. Flagellin

The component protein of the filament is called flagellin. Although the flagellum of many bacteria is composed of one kind of flagellin, some flagella consist of more than two kinds of closely related flagellins. The molecular size of flagellin ranges from 20 to 60 kDa. Enterobacteria tend to have larger molecules, whereas species living in freshwater have smaller molecules.

One of the most characteristic features of flagellin is evident even in the primary structure of the molecule; the amino acid sequences of both terminal regions are well conserved, whereas that of the central region is highly variable even among species or subspecies of the same genera. As a matter of fact, this hypervariability of the central region gives rise to hundreds of serotypes of *Salmonella* spp.

The terminal regions are essential for binding of each molecule to another to polymerize them into a filament. Complete folding of flagellin occurs during assembly; although the terminal regions do not take on any specific secondary structure in solution, they are converted into α -helix after polymerization.

In the filament, the terminal regions are located at the innermost radius of a cylindrical structures, whereas the central region is exposed to the outside. Note that the filament is extremely stable; it does not depolymerize in water, in contrast to actin filaments or tubulin filaments, which depolymerize in the absence of salts.

This description of the flagellin molecule is not applicable to that found in archaeobacteria. Archaic flagella seem to have a system totally different from those of eubacteria; archaic flagellins have signal sequences, suggesting that the flagellum might grow from the proximal end in the outer membrane, in contrast to the distal growth of eubacterial flagellum (see Section IV).

4. Cap protein

Flagella have been regarded as a self-assembly system. Indeed, flagellin can polymerize into flagella under conditions that commonly promote protein crystallization *in vitro*. However, *in vivo* flagellin assembly requires another protein, without which the flagellin is secreted into the medium as monomers. The protein that helps filament formation is located at the tip and is thus called the cap protein, or HAP2 or FliD.

The cap proteins assemble in a pentamer, forming a star-shaped structure. The star hands fit in the grooves of flagellin subunits at the tip of flagellum, leaving a small gap for a nascent flagellin to insert.

B. Hook

1. Shape

Hook, as the name suggests, is more sharply curved (almost in a right angle) than the filament and is much shorter. The curvature indicates the flexibility of the hook, although it has to be stiff enough to transmit the torque generated at the basal structure to the filament. From these physical properties, the hook has been regarded as a universal flexible joint.

The length of the hook is 55 nm with a standard deviation of 6 nm, which is rather well controlled when compared with the length of filament. The hook length is not controlled by any molecular rulers, as might have been expected, but by a measuring cup at the base of the flagellum (see Section IV).

A polyhook is a hook of indefinite length, obtained in certain kinds of mutants. Its shape is a right-handed superhelix. The wild-type hook has the same superhelix, but consists of about one-fourth of the helical pitch.

2. Hook protein

The hook is a tubular polymer made of a single kind of protein, hook protein or FlgE. The molecular size of hook protein varies from 29 kDa (*Bacillus subtilis*) to 76 kDa (*Helicobacter pylori*), but it is around 42 kDa for most species.

The architecture of hook protein resembles that of flagellin—the amino acid sequence in both terminal regions is well conserved, but in the central region it is variable. Hook protein folding also completes on assembly.

3. Scaffolding protein FlgD

The hook does not self-assemble; it requires a helper protein, FlgD, which functions in a similar way that FliD does for filament formation. FlgD sits at the tip of the nascent hook to polymerize the hook protein coming out from the central channel. When the hook length reaches 55 nm, FlgD is replaced by HAP1 (FlgK), which remains in the mature flagellum. Because of its temporary existence, FlgD is regarded as a scaffolding protein.

4. Hook-associated proteins

There are two minor proteins between the hook and filament. They are called hook-associated proteins (HAPs) because they were found at the tip of the hook in several filamentless mutants. There were originally three HAPs, called HAP1, 2, and 3, in the order of their molecular size. HAP2 turned out to be located at the tip of filament as described above, leaving HAP1 and 3 between the hook and filament. They are, therefore, better termed hook-filament junction proteins.

The number of subunits of HAP1 and 3 in a filament is estimated to be 5 or 6, indicating that they form one-layer rings sitting one on another.

The roles of these two HAPs have been ambiguous. The idea of a connector to smooth the junction between the two polymers is blurred by the question, “Why are not one but two kinds necessary?” In a mutant of HAP3, filaments underwent polymorphic transitions so easily that cells cannot swim smoothly, suggesting a specific role of HAP3 as a stabilizer of filament structure.

C. Basal structure

Flagella have to be anchored in the cell wall. The structural entity for the anchoring was called the basal structure or basal granule, hinted at by vague images by electron microscopy. Since DePamphilis and Adler in 1974 defined the details of the basal structure, it has been called the basal body. The basal body typically consists of four rings and one rod.

The basal body does not contain everything necessary for motor function. Fragile components were detached from the basal body during purification.

In 1985, one such fragile structure was found attached to basal bodies purified by a modified method; it was named the C (cytoplasmic) ring. In 1990, another rod-like structure was found in the center of the C ring. Therefore, the basal structure (as of 2003) consists of the basal body, the C ring, and the C rod, but there may be more.

1. Basal body

The basal body contains rings and a rod penetrating them. The number of rings varies depending on the membrane systems; there are four rings in most gram-negatives, and two rings in gram-positives, exemplified by *B. subtilis*. Some variation in the number (such as five rings in *C. crescentus*) has been occasionally seen, but the purpose and function of a fifth ring is unclear because the cell's membranes are supposed to be the same as those of *S. typhimurium* or *E. coli*.

The structure of the basal body of *S. typhimurium* has been extensively analyzed. The physical and biochemical properties of the substructures of the basal body described later are from *S. typhimurium*, unless otherwise stated.

2. LP-ring complex

The outermost ring, the L ring, interacts with the lipopolysaccharide layer of the outer membrane, and the P ring just beneath the L ring may bind to the peptidoglycan layer. The LP-ring complex works as a bushing, fixed firmly enough to hold the entire flagellar structure stably in the cell surface.

The component proteins, FlgH for the L ring and FlgI for the P ring, have signal peptides, indicating that they are secreted through the general secretory pathway (GSP), which is the exception for flagellar proteins (see Section IV). FlgH undergoes lipoyl modification.

After the L and P rings have bound together to form the LP-ring complex, this complex is resistant to extremes of pH or temperature. Subjecting it to pH 11, pH 2, or boiling for 1 min does not destroy the complex, confirming that the complex serves as a rigid bushing in the outer membrane.

The essential roles of the complex are still ambiguous because mutants lacking the complex still can swim, though poorly, and because no corresponding structure has been found in gram-positive bacteria.

3. MS-ring complex

Earlier studies of flagellar motor function assumed that torque would be generated between the M and S

rings, which face each other on the inner membrane. However, in 1990, it was shown that a single type of protein, FliF, self-assembles into a complex consisting of the M and S rings and part of the rod.

FliF is 65 kDa, the largest of the flagellar proteins. It contains no cysteine residues. It consists of several regions—terminal regions and two distinguishable central regions. Overproduction of FliF in *E. coli* gives rise to numerous MS-ring complexes packed in the inner membrane.

The S ring has been seen in the basal bodies from all the species studied so far (at least seven examples). It stays just above the inner membrane (supramembrane) and has no apparent interaction with any other structures. Besides, it is very thin (~1 nm), and the role of the S ring remains mysterious.

Although the MS-ring complex is no longer regarded as the functional center of the flagellar motor, it is still the structural center of the basal structure and plays an important role in flagellar assembly (see Section IV).

4. Rod

The rod is not as simple as its name suggests; it consists of at least four distinct proteins. It breaks at the midpoint when external physical force is applied to the filament, which is not expected in a structure that transmits torque to the filament.

Rod formation seems complicated because of the four component proteins. No intermediate rod structure has been observed; either there is a whole rod or no rod at all.

Because the P ring is formed on the rod, some of the rod proteins could be the target of interaction with FlgI, the subunit of the P ring.

5. C ring

The C ring is a fragile component of the basal structure. It is resistant to the nonionic detergent Triton X-100, but it is destroyed by the alkaline pH and high salts concentration employed by conventional purification methods. The dome shape of the C ring is easily flattened on a grid during preparation for electron microscopy.

The C ring consists of the switch proteins (FliG, FliM, and FliN) and so is sometimes called the switch complex. It is not known whether other proteins are present or not. FliG directly binds to the cytoplasmic surface of the M ring. FliM binds to FliG, and FliN to FliM. The stoichiometry of these molecules in the C ring is still controversial; 20–40 copies of FliG, 20–40 copies of FliM, and several 100 copies of FliN.

Genetic studies revealed that the switch complex plays important roles in flagellar formation, torque generation, and the switching of rotational direction. The C ring directly binds signal molecules, CheY, produced in the sensory transduction system, but the mechanism of the switching is ambiguous.

6. Export apparatus

Flagella have been regarded as having a self-assembly system, similar to that of bacteriophages. However, flagellar assembly is quite different from phage assembly in many ways. First, the flagellum, being an extracellular structure, assembles not in the cytoplasm but outside the cell. Second, the component proteins therefore, have to be transported from the cytoplasm to the outside. Third, assembly consequently proceeds in a one-by-one manner, at the distal end of the nascent structure.

For this kind of assembly, a protein excretion system must play an important role. As a matter of fact, among the 14 genes required in the very first step of flagellar assembly, at least seven gene products are necessary to form a protein complex, called an export apparatus. One of them, FliI, has an ATPase activity, suggesting that one step in the export process requires ATP hydrolysis as an energy source. The physical body of the export apparatus has not been identified; the C rod is a strong candidate, judging from its location in the C ring.

II. FUNCTION

The function of flagella is described here briefly so that the meaning of the structure can be understood.

Bacterial flagella rotate. There is no correlation between bacterial flagella and eukaryotic flagella, either in function or in structure; the type of movement, the energy source, and the number of component proteins differ greatly between the two. No evolutionary correlation between these two types of flagella has been shown.

Among motile bacterial species, swimming by flagellar rotation is the most common. However, several families such as myxococcus, mycoplasma, and cyanobacteria can move on a solid surface in a gliding motion; the motile organ of gliding bacteria is not known.

A. Torque

The rotational force (torque) of the flagellar motor is difficult to measure directly, but can be estimated

from the rotational speed of flagella. The method most widely employed is the tethered-cell method, in which the rotation of a cell body caused by a tethered filament can be observed with an ordinary optical microscope. A more sophisticated method, which employs a laser as the light source of a dark-field microscope, allows one to measure the rotation of a flagellum on a cell stuck on the glass surface at a time resolution of millisecond.

1. Rotational direction

The flagella of many species (e.g., enterobacteria) can rotate both clockwise (CW) and counter-clockwise (CCW). Under ordinary circumstances, around 70% of the time is occupied by CCW rotation, which causes smooth swimming. A brief period of CW rotation causes a tumbling motion of the cell. There is no perceptible pause in switching between the two modes.

In some bacterial species such as *Rhodobacter sphaeroides*, a lateral flagellum on a cell rotates in the CW direction only, with occasional pauses. During the pauses, the filament takes on a coiled form and curls up near the cell surface. Upon application of torque to this filament, the coiled form extends to a semi-stable right-handed form that closely resembles a curly form. The CW rotation of this right-handed helix causes a forward propulsive force on the cell.

2. Rotational speed
